Cumulatively, up to 20% of children with severe obesity have rare chromosomal abnormalities and/or highly penetrant genetic mutations that drive their obesity.[78] This figure is likely to increase with wider accessibility to genetic testing and as new genes are identified from exome and genome sequencing. A genetic diagnosis can inform management (many such patients are relatively refractory to weight loss through changes in diet and exercise) and can inform clinical decision-making regarding the use of bariatric surgery (feasible in some; high-risk in others). Importantly, some genetic obesity syndromes are treatable. Recombinant leptin is dramatically effective at treating the severe obesity of congenital leptin deficiency. Setmelanotide, an MC4R agonist, has been used effectively in phase II/III clinical trials of POMC and LEPR deficiencies and is being explored for the treatment of other genetic obesity syndromes affecting the melanocortin pathway. Ultimately, understanding how these pathways are disrupted in people with weight problems may inform strategies to target these pathways for prevention and treatment.

POSTABSORPTIVE INTERMEDIARY METABOLISM

Introduction

All major body processes require energy, which is provided by intermediary metabolism, the conversion of nutrient-derived substances into forms that can be combusted to yield energy immediately or after a period of storage, and that collaterally can generate substrate for use in anabolic processes. A useful definition of *postabsorptive metabolism* is a time when energy needs are being met through mobilization of endogenous substrates, after digestion, absorption, tissue distribution, oxidation, and storage of ingested food has been completed (*postprandial metabolism*). A typical duration of postprandial metabolism is at least a few hours, as many as 6 or more, depending upon the size and composition of the meal. Accordingly, if one daily meal is consumed, postabsorptive metabolism would stretch for 18 or more hours of a day. More commonly though, two to three meals are consumed in a day, the successive postprandial phases often fuse one into the next (especially for postprandial lipoprotein metabolism), and the postabsorptive phase may comprise as few as 8 hours of the daily cycle of eating and fasting.

A striking characteristic of postabsorptive metabolism is that circulating metabolite concentrations remain quite stable, which is sharply different from the dynamic changes that characterize postprandial metabolism. The stability of metabolite concentration is particularly evident for plasma glucose, and somewhat less so for plasma free fatty acids (FFAs), which have a day-to-day variance of approximately 30%, as well as a greater variability for intermediary metabolites such as lactate and ketones. Intuitively, it is appreciated that a stability of circulating levels of substrates during postabsorptive metabolism does not infer metabolic stasis, even though metabolic rates and energy expenditure are at a relative nadir during resting postabsorptive conditions. Rather, constancy of circulating substrate concentrations reflects the underlying presence of tightly governed rates of substrate flux. Flux can be considered regarding a single enzymatic reaction or along an enzymatic pathway, but in the current context substrate flux refers to its rate of appearance into plasma (from endogenous stores and newly synthesized substrate) and rate of utilization, more commonly termed rate of disappearance, from plasma into tissues.[1] A persisting stability of substrate concentrations in plasma derives from a well-balanced equivalency between rates of appearance and disappearance. Briefly, determinations of substrate flux can be performed using an isotopically labeled metabolite and measurement of its dilution in the unlabeled (endogenous) pool. This is a largely a research method rather than a clinically pragmatic determination, but an understanding of the findings, qualitatively and, in select instances, quantitatively, provides mechanistic insights for understanding postabsorptive intermediary metabolism. Physiological governance of flux will be one focus of this section, with emphasis upon its endocrine regulation, and this understanding of flux and interorgan exchange begins with a review of the energy stores of fat, carbohydrate, and protein within the major tissues, as shown in Table 22.1.

A second key characteristic of postabsorptive metabolism is an approximate and sustained balance between the oxidation of carbohydrate versus that of lipid. This balance between glucose and fat oxidation is not a true equipoise, as approximately 60% of energy production derives from fat oxidation. But this sustained pattern too is a sharp difference from postprandial metabolism, where there is a pronounced

TABLE 22.1 Fuel Reserves in a Prototypical 70-kg Male

	AVAILABLE ENERGY (kcal)		
Organ	**Glucose or Glycogen**	**Free Fatty Acids or Triglycerides**	**Protein**
Blood	18	80	0
Liver	400	450	400
Brain	8	0	0
Adipose	80	135,000	40
Muscle	1200	350	24,000

early suppression of fat oxidation and stimulation of glucose oxidation, with a more gradual resumption of fat oxidation and coordinate decline of glucose oxidation as the transition toward postabsorptive metabolism begins to occur. Delineating the tissue responsible for glucose and fat oxidation will also be a focus of this section, and in relation to overall rates of energy expenditure. As a prelude, the concept to be developed is that endocrine governance of substrate oxidation during postabsorptive metabolism is mostly indirect, in the sense that rates of glucose uptake and oxidation are not directly insulin-stimulated (as opposed to postprandial conditions), nor is fat oxidation directly controlled by endocrine signals. Instead, glucose uptake and oxidation are largely "insulin-independent," and that of fatty acids is substrate-driven, with endocrine control exerted through governing rates of release of glucose and fatty acids. A schematic depicting the primary systems involved in postabsorptive energy metabolism is shown in Fig. 22.1.

Resting Energy Expenditure and Postabsorptive Respiratory Quotient

Energy expenditure is comprised of three principal components: resting energy expenditure (REE), physical activity, and the thermic effects of food ingestion.[2] The rate of REE is approximately 1 kcal/min, or approximately 1400 to 1500 kcal per day. REE accounts for approximately 60% of daily energy expenditure, and the thermic effect contributes approximately 10%, but considering that energy expenditure due to physical activity can vary greatly, these proportionalities are generalizations. Notably, REE is proportional to body size, revealing strong linear correlation with fat-free mass, which is comprised of the more metabolically active tissues. This is similar for fasting rates of hepatic glucose production (HGP; discussed subsequently). Thus, both REE and HGP reveal a vital communication between body composition, the tissues that mostly define energy requirements, and governance of postabsorptive metabolism.[3] However, as will also be addressed, the relationship between fat mass and rates of fatty acid flux is less rigorous than that for the relationships of HGP or REE and fat-free mass.

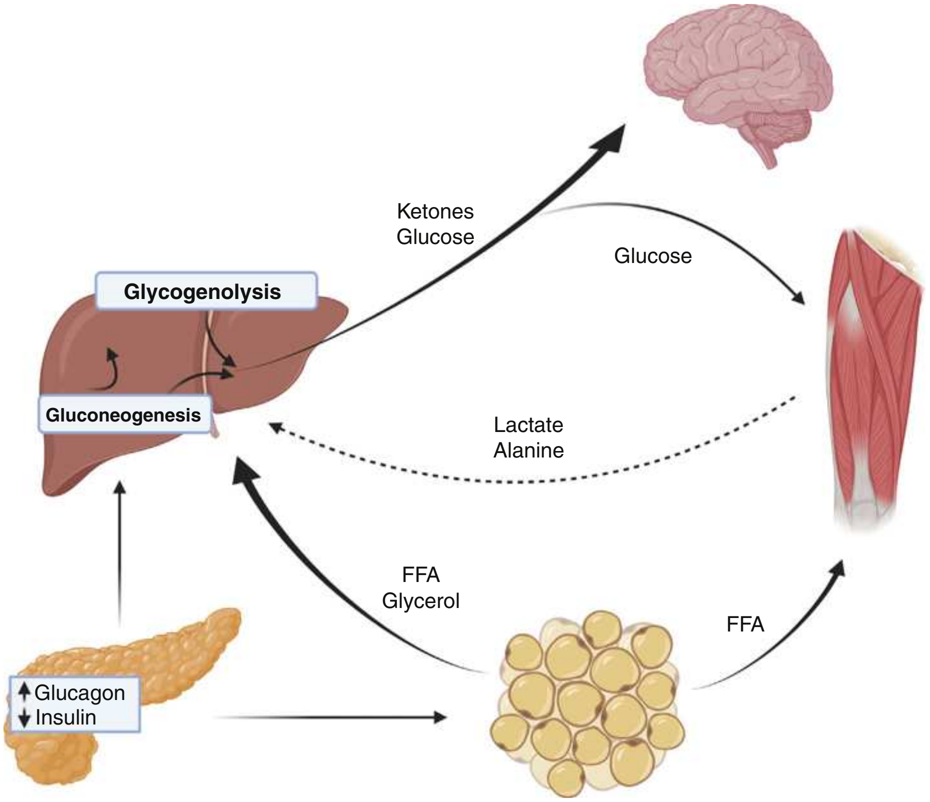

Fig. 22.1 **Postabsorptive (fasting) metabolism.** The driver of glucose flux during postabsorptive intermediary metabolism is hepatic glucose production, control over which is mediated by a relatively low ratio of insulin to glucagon. Because of low peripheral circulating insulin and in relation to the molecular physiology of tissue glucose transporter, glucose utilization in peripheral tissues is largely insulin-independent, and, apart from the central nervous system, is lower than the utilization of fatty acids. Low peripheral circulating insulin enables lipolysis in adipose tissue to proceed supporting a rate of free fatty acid (FFA) flux that is roughly double the circulating energy equivalence of that for glucose and underlying the 60% contribution of fat oxidation to resting rates of energy expenditure.

Measurement of REE (and the other components of energy expenditure) is most commonly performed by measurement of oxygen consumption and carbon dioxide production using the method of indirect calorimetry. An alternative is a doubly-labeled water isotopic method that can be used over short intervals in freely living individuals.[4] Each approach has advantages and limitations. One of the advantages of indirect calorimetry is that it can provide much more finite or precise temporal resolution of patterns of energy expenditure and substrate oxidation rates. Gas exchange can be measured in dedicated, specifically engineered calorimetry chambers, or less precisely but more accessibly at the bedside with a hood canopy or on a treadmill with a mouthpiece to collect respired air that feeds into gas analyzers. The equations of calculation of energy expenditure are referenced, together with a critique of some of the nuances and limitations of indirect calorimetry.[5] Beyond its use in metabolic research, one of the pragmatic clinical uses of indirect calorimetry is in assessing metabolic responses to enteral or parenteral nutrition in critically ill patients. Using these determinations, the quotient of carbon dioxide (CO_2) production to oxygen (O_2) consumption can be examined; this is termed the respiratory quotient (RQ). Values for RQ denote the relative reliance upon carbohydrate versus lipid oxidation, and with some additional determinations (e.g., urinary nitrogen), the contribution of protein oxidation, usually a modest clarifying adjustment, can also be estimated. Using rates of O_2 consumption, CO_2 production, and urinary nitrogen, actual rates of glucose and fat oxidation can be calculated. However, to examine concepts germane to integration of glucose and fat oxidation during postabsorptive and postprandial conditions (as well as during exercise), the RQ itself is a useful and straightforward parameter. The principles underlying the RQ stem from the chemical composition of oxidative substrates. Oxidation of glucose (a polymer of six CH_2O) to six CO_2 and six H_2O requires a consumption of an equimolar quantity of six O_2; hence, the corresponding RQ has a value of 1.0. Oxidation of fatty acid (a polymer of CH_2 units) requires a proportionately greater amount of oxygen for complete combustion and yields approximately in 7 moles of CO_2 production relative to a requirement for 10 moles of O_2 consumption; hence, the RQ for fat oxidation is 0.70. Intermediate RQ values reflect an admixture of glucose and fat oxidation. In a lean, healthy human, a typical fasting RQ value is in the range of 0.78 to 0.83. It can be estimated from this range of RQ that, during resting postabsorptive conditions, the oxidation of fat provides energy that accounts for approximately 60% of REE.

KEY POINTS: Resting Energy Expenditure

- Resting energy expenditure (REE) is approximately 1 kcal/min, 1400–1500 kcal/day, though proportional in amount to fat-free mass, which contains the metabolically active tissues that contribute to REE.
- REE generally accounts for approximately 60% of daily total energy expenditure, though the proportion will vary in relation to levels of energy expended in physical activity.
- Measurement of oxygen consumption and carbon dioxide production for estimation of energy expenditure also can be used to estimate respective rates of glucose and fat oxidation.

Postabsorptive Glucose Utilization

There is a well understood persistent and obligate requirement of the central nervous system (CNS) for glucose uptake from plasma and its oxidation to meet its bioenergetic needs. The brain does not store glycogen, and without continuous glucose delivery becomes deprived of its requisite substrate. This rate of CNS glucose uptake is approximately 70 to 80 mg/min or approximately 1 mg/min-kg body weight of glucose flux, which is about half of the postabsorptive rate of glucose flux (as further described). The predominant glucose transporter of the CNS is GLUT3, a high-affinity (low Km) glucose transporter, and as such GLUT3 maximizes glucose transport within the normal (i.e., euglycemic) range of fasting plasma glucose.[6] CNS glucose uptake is not further increased at higher plasma concentrations, as during postprandial conditions. As a further consequence of this molecular physiology of GLUT3, CNS glucose uptake can become critically reduced with a 25% to 30% reduction in fasting plasma glucose concentrations, as there is a sharp decline in CNS glucose uptake as plasma glucose concentration declines to levels lower than this.

Due to the properties of GLUT3, glucose uptake and oxidation by the brain is categorized as "insulin-independent," as is the great majority of the remaining glucose flux during postabsorptive conditions. Other than the brain, there is no single peripheral tissue that predominates in rates of postabsorptive glucose uptake; instead, glucose uptake is dispersed somewhat evenly across tissues, each at a relatively low rate and with an obligate need by red blood cells. Only a minor proportion of the peripheral tissues' (i.e., non-CNS) directed glucose flux, also approximately 1 mg/kg-min, undergoes oxidation; instead, it is mostly metabolized by glycolysis to the level of trioses (e.g., pyruvate and interconversion to lactate), while some undergoes a transamination reaction to form alanine, and these trioses reenter circulation as part of an interorgan exchange. A major fate is as a substrate for gluconeogenesis in the liver, completing an ongoing, recurring cycle within postabsorptive metabolism.

KEY POINTS: Molecular Physiology of Glucose Transporters as a Determinant of Glucose Utilization During Postabsorptive Conditions

- GLUT3, expressed in the CNS, is a high-affinity isoform that maximizes glucose uptake across the normal range of fasting glucose and does not further increase as blood glucose rises.
- GLUT4, expressed in skeletal muscle, heart, and adipose tissue, is sequestered in cytosolic vesicles under resting postabsorptive conditions, leading to low rates of glucose use by these tissues.
- GLUT2, expressed in liver and in pancreatic β cells, is a low-affinity isoform that enables blood glucose–dependent rates of transport, an attribute that further serves as a glucose sensor within these tissues that have key roles in responding to blood glucose changes.

Postabsorptive Fatty Acid Utilization

Nearly all tissues and organs have a capacity to oxidize fatty acids, with notable exceptions being red blood cells that lack mitochondria and the CNS, due to inability of fatty acids to traverse the blood–brain barrier. Kidney, heart, and liver are key tissues accounting for uptake and oxidation of fatty acids during postabsorptive metabolism, as is skeletal muscle. The persistent reliance of the CNS on glucose oxidation has already been stated, and, in an integrated physiology context, it is fat oxidation that accounts for a major proportion of energy production in peripheral tissues during postabsorptive conditions; as noted earlier, it accounts for approximately 60% of REE.

It is worthwhile to delve a bit deeper into skeletal muscle metabolism, as an example of a tissue that has a high postabsorptive utilization of fatty acids and yet also has a high capacity for glucose utilization, a capacity to transition or toggle between fuels that is manifest by other tissues, though perhaps not in as pronounced a manner as skeletal muscle. Thus, skeletal muscle has a robust capacity to "switch" fuels, and this metabolic flexibility is an important manifestation of metabolic health,[7,8] in appraising governance and response in transitions between postabsorptive and postprandial metabolism. The governing of this switching of fuels will be more fully addressed later.

During resting postabsorptive conditions, skeletal muscle has a quite low rate of glucose uptake and relies instead chiefly upon fatty acid oxidation. It has been estimated, based on arteriovenous differences across an arm or a leg (tissue beds that are predominated by, though not exclusively comprised of, skeletal muscle) that fractional extraction of plasma glucose is only 1% to 2%, whereas that for plasma fatty acids is approximately 30% to 35% during resting postabsorptive conditions.[9] The low rate of glucose usage by skeletal muscle during fasting conditions is attributable to low circulating insulin levels during postabsorptive conditions, inadequate to stimulate glucose uptake by skeletal muscle. Moreover, during fasting conditions there is a net efflux of pyruvate, lactate, and alanine from skeletal muscle, that as an aggregate molar amount of efflux approximates the uptake of glucose, leaving a net zero balance for glucose-derived carbons. The uptake and glycolytic metabolism of glucose by skeletal muscle, returning lactate to venous blood and for uptake in the liver as a substrate for gluconeogenesis, represents the well-described Cori cycle.[10] There is as well a low intrinsic rate of glycogenolysis in resting skeletal muscle, which contrasts with more active postabsorptive glycogenolysis in liver. Though muscle glycogen reserves, which in aggregate approximate 400 g (dry weight), are abundant and constitute approximately 80% of systemic glycogen reserves, the pool is held for mobilization in response to physical activity, especially strenuous exercise, as will be delineated later. Furthermore, skeletal muscle lacks glucose-6-phosphatase and cannot release free glucose.

A series of now classic human physiology studies identified that fatty acid oxidation is the principal energy source of resting skeletal muscle during postabsorptive conditions.[11] This finding was based upon the measurement of the RQ across the forearm, based on regional determinations of O_2 uptake and CO_2 production across the limb (rather than the systemic gas exchange earlier described). An RQ value in the range of 0.70 to 0.76 was observed in healthy, lean individuals, lower than systemic RQ (not surprising given the exclusion of CNS glucose oxidation from the regional measurement) and denoting a nearly exclusive reliance upon fat oxidation. Skeletal muscle, like most nonadipose tissues, does contain lipid droplets (LDs), comprised mostly of triglyceride (TG), and fatty acids can be mobilized from these droplets, as well as exchange with the TG in the droplets on uptake into myocytes, and uptake of plasma FFAs is the principal source for oxidation during resting postabsorptive conditions.

The uptake of FFAs into skeletal muscle and other tissues is not directly governed by hormonal actions at the sarcolemma, unlike the direct actions of insulin to stimulate glucose transport into muscle; rather, endocrine governance of fatty acid uptake into muscle and other tissues is indirect, mediated by endocrine control of lipolysis, and hence governance of plasma FFA concentrations. Plasma concentration of FFAs is the key factor governing rates of uptake into muscle and other tissues. During postabsorptive conditions, a typical circulating concentration of plasma FFAs is 0.5 mmol/L, or approximately one tenth the molar concentration of plasma glucose. Moreover, FFAs, being strongly hydrophobic molecules, circulate noncovalently bound to albumin; there are generally one to three fatty acids bound per albumin molecule at concentrations common in postabsorptive conditions. Fatty acids taken up by tissues are from the much smaller "free fraction" of unbound fatty acids that exists in equilibrium with albumin-bound fatty acids.

A comparison of the respective concentrations of glucose and FFAs in plasma (e.g., 5.0 vs. 0.5 mmol/L, respectively) as an index of relative availability during postabsorptive metabolism is somewhat misleading, because it overlooks the respective underlying rates of glucose and FFA flux. As earlier noted, a typical postabsorptive rate of plasma glucose flux is 2 mg/min-kg body weight (10 μmol/min-kg body weight; in aggregate approximately 700 μmol/min for a 70-kg individual). The rate of appearance of fatty acids into plasma is not too dissimilar, at approximately 1.7 mg/min-kg (6–8 μmol/min-kg body weight; in aggregate approximately 400–500 μmol/min in a 70-kg individual).[12,13] This rough equivalency in flux, somewhat lower for fatty acids than for glucose, reflects a more rapid turnover rate (shorter half-life) for FFAs than for glucose; the half-lives are 2 minutes and 15 minutes, respectively, for plasma FFAs and glucose. Also, the higher energy density of FFA relative to glucose (9 compared with 4 kcal/g, respectively) means that the potential circulating energy yield of FFA is nearly twice that of glucose. Taking each of these factors into consideration and recognizing the considerably more rapid turnover rate of the plasma FFA pool than that of glucose, it can be more clearly understood how it is that the oxidation of plasma FFAs accounts for approximately 60% of REE during postabsorptive conditions, despite an order of magnitude difference in plasma concentrations and an exclusive use of glucose by the CNS.

To delve a bit further into postabsorptive kinetics of glucose and fatty acid flux, it was earlier pointed out that rates of fasting HGP are linearly proportional to body weight, and more tightly so to fat-free mass. There is a linear relationship between postabsorptive rates of fatty acid rate of appearance and fat mass, the latter reflecting of course the tissue of origin from which fatty acids are released via lipolysis. This correlation accounts for roughly 40% of the interindividual variance in postabsorptive fatty acid flux, at least across a cohort of men and women ranging from lean to obese,[14] so it is an association of moderate strength only. Also, of interest, there is a rather strong negative, curvilinear correlation between postabsorptive fatty acid flux (normalized to per kg fat mass) and obesity, suggesting that the rate of release of fatty acid from adipose, per unit weight of fat, is reduced in obese relative to leaner individuals. Another way to express this is that, in lean individuals, the mobilization rate (i.e., lipolytic rate) per kilogram of fat mass is substantially accelerated compared with that in obese individuals. Yet, despite this, plasma fatty acid levels tend to be somewhat increased in obese compared with lean individuals, and thus, even though there appears to be a per unit of fat greater stringency in control of lipolysis, this does not appear to fully compensate for the overall expansion of fat mass. There are also findings indicating that body fat topography is associated with variances in rates of postabsorptive fatty acid flux, with higher rates in obese women who have an upper body fat distribution compared with obese women with a lower body fat distribution, the latter not differing in postabsorptive fatty acid flux from lean women.[15]

At the cellular level, unbound FFAs enter a cell down a concentration gradient (plasma to cytosol) by "flip-flop" diffusion across the cell membrane, and there is facilitation by tissue-specific families of fatty acid transporters. Once within the cytosol, fatty acids noncovalently bind to fatty acid–binding proteins, which protects the cell from detergent-like, damaging properties of unbound FFAs. Intracellular fatty acids are quickly "activated" by esterification to CoA, to form fatty acyl-CoA, an adenine triphosphate (ATP) requiring reaction catalyzed by the enzyme acyl-CoA-synthase, a reaction that is essential in maintaining a concentration gradient relative to plasma. Fatty acyl-CoA can be partitioned toward reesterification to form TG in LDs or other pathways of lipid synthesis (e.g., phospholipids, sphingolipids), but during postabsorptive conditions a considerable fraction are partitioned toward β-oxidation. β-oxidation is a repeating four-step catabolic set of enzymatic reactions that, with each cycle, progressively cleaves the full-length fatty acid into two-carbon fragments, acetyl-CoA moieties, which can then enter the TCA cycle to complete final oxidation. Both processes occur within the mitochondria matrix, yet fatty acyl-CoAs are unable to diffuse across the outer and inner mitochondrial membranes, which possess a phospholipid composition unique from that of the cell membrane. Instead of diffusion, a specific a three-component transport complex, the carnitine-palmitoyl transferase complex (CPT), mediates this entry of fatty acyl-CoA. Greater details of the intracellular catabolism of fatty acids are beyond the scope of this chapter, but the biochemistry is well described.[16]

There is one aspect of this molecular physiology that warrants highlighting, because it is a fulcrum for the governance of fat oxidation, and hence pivotal as well in the governance of intermediary metabolism. This aspect is the role of malonyl CoA in allosteric modulation of the activity of CPT-1, the enzyme that mediates transfer of an acyl moiety from acyl-CoA to carnitine, and it is the carnitine-acyl that is shuttled into the mitochondrial matrix, where acyl-CoA is reformed before entry into the β-oxidation cycle. The activity of CPT-1 is strongly inhibited by malonyl CoA, though there are some tissue differences in this sensitivity, with the isoform of CPT-1 in skeletal muscle being more sensitive to malonyl CoA inhibition than the isoform in liver. Malonyl CoA is a crucial intermediate in the process of *de novo* lipogenesis, derived in turn from a surfeit of acetyl-CoA, generated by glycolysis and hence conversion from pyruvate. Even in tissues like skeletal muscle that have a low overall capacity for *de novo* lipogenesis, the generation of malonyl CoA serves an important substrate-based signaling function in a reciprocal on-off toggling of glucose and fatty acid oxidation.[17]

During postabsorptive conditions, malonyl CoA concentrations in skeletal muscle (and other tissues) are low, and CPT-1 is unimpeded, and this, together with relatively avid uptake of plasma fatty acids, drives fat oxidation. Glucose oxidation is low, due primarily to the low rates of glucose uptake and glycolysis, and activity of the pyruvate dehydrogenase complex, which catalyzes formation of acetyl-CoA (for entry into the TCA cycle) from pyruvate upon the latter's entry into mitochondria, is correspondingly low as compared with insulin-stimulated conditions.

In the liver, the good availability of fatty acids during postabsorptive conditions, low concentrations of malonyl CoA, and, thus, relatively unimpeded CPT complex activity, create conditions wherein a surfeit of acetyl-CoA derived from β-oxidation of acyl-CoA can give rise to ketogenesis. Ketone bodies are the most water-soluble form of lipid-derived metabolites and are formed in the liver from the condensation of two acetyl-CoAs. Ketones (acetoacetate and β-hydroxybutyrate) can be utilized by numerous tissues and production rates, and blood concentrations rise with prolongation of fasting. With prolonged fasting, the CNS adapts for utilization of ketones, which provides an additional mechanism for sparing the use of glucose. Clinically, in severe insulin deficiency, accelerated rates of ketone production cause diabetic ketoacidosis.

KEY POINTS: Postabsorptive Fatty Acid Rate of Appearance and Utilization

- Usual concentrations of plasma fatty acids are one tenth of those of plasma glucose, but the rate of appearance (in mg/min-kg body weight) is roughly equivalent to glucose, and the energy yield is nearly 2-fold higher than for glucose.
- The half-life of plasma fatty acids is just 2 min, nearly an 8-fold more rapid turnover of plasma fatty acids than glucose.
- As a fraction of stored triglyceride in adipose tissue, the rate of lipolysis is a miniscule fraction (~10^{-5}), a thousandth of the rate of release of hepatic glycogen, reflecting tight, minute-to-minute governance of lipolysis.
- The endocrine control of lipolysis mostly represent the opposing actions of insulin (restraining) and catecholamines (stimulating) lipolysis.

Lipolysis and Control of Fatty Acid Availability During Postabsorptive Conditions

In the introduction to this section on postabsorptive intermediary metabolism, emphasis was placed upon the stability of fasting substrate concentrations, especially that of plasma glucose. In comparison, greater variability on a day-to-day basis is observed for plasma concentration of fatty acids, and this greater variability relative to glucose can also be observed within any given interval of postabsorptive metabolism, wherein fluctuations of plasma fatty acid concentrations are more evident than those for glucose. However, a conclusion that governance of fasting rates of fatty acid flux is less stringent than that of fasting rates of glucose flux is arguably incorrect, and the context to refute this notion is outlined here. A first context is to consider the size of the potential fatty acid pool (i.e., the reservoir of stored TG) and the extent to which a fasting rate of fatty acid flux represents a fractional turnover of this pool. Second, the rapid turnover rate of plasma fatty acids (half-life of approximately 2 minutes) is such that any modulation of rates of appearance of fatty acids quickly resettles into a near steady-state equilibrium and can accordingly manifest as a change in fatty acid concentration. Thus, a change in plasma fatty acids reveals acute changes in the level of control of lipolysis, and perhaps as well variance in rates of clearance by tissues of utilization, not *per se* a loss or absence of control. Third, and as will be delineated next, the specific steps controlling lipolysis are multifaceted and complex and, while still very much an area of new discoveries, denote intricate governance.[18]

Even in a lean individual there is a considerable reserve of stored energy in the form of TG in white adipose tissue. In a 70-kg lean adult, fat mass comprises approximately 10% of body weight in a man and somewhat more, approximately 30% in a healthy lean woman; certainly, these percentages are much greater in overweight and obese men and women. Each gram of fat, fully combusted, yields 9 kcal; thus, 7 kg of fat mass in a lean, 70-kg male or 20 kg of fat mass in a lean, 70-kg woman equates to a potential energy reserve (estimated at 7,700 kcal/kg adipose) of 77,000 kcal and 231,000 kcal, respectively, in a man or a woman. This far exceeds the caloric equivalent of 400 kcal corresponding to a replete hepatic glycogen content of 100 g and the 1600 kcal corresponding to a replete skeletal muscle glycogen content of 400 g. Thus, a fatty acid flux of approximately 120 mg/min in a 70-kg adult represents a small minute-to-minute fractional release (turnover) of the 10 to 15 kg of adipose tissue in a man or woman.

In white adipose tissue, adipocytes contain one large LD with a narrow perimeter of cytosol and organelles. The hydrophobic core of the LD is largely TG, its surface covered by a phospholipid monolayer coated with protein chaperones, notably perilipins, that can, in a regulated manner, constrain access by lipases to TG.[18] There are three key lipases that can carry out lipolysis of TG in a LD. These start with adipose triglyceride lipase (ATGL): TG is its preferred substrate, its activity is modulated by a protein cofactor, release of which is governed by and related to conformational changes in perilipins induced by endocrine stimulators of lipolysis, and its reaction yields a fatty acid and diacylglycerol. Upon the latter, hormone-sensitive lipase (HSL) next acts to yield a fatty acid and monoacylglycerol, and HSL activity, which has been well-studied, is increased by endocrine stimulators of lipolysis and inhibited by insulin, the endocrine suppressor of lipolysis. The third lipase is monoacylglycerol lipase, which cleaves the remaining fatty acid and thereby also yields glycerol.

The overall yield of lipolysis is three fatty acids and free glycerol. Free glycerol exits the adipocyte and serves as a gluconeogenic precursor in the liver. Increased cyclic adenosine monophosphate (cAMP) or cyclic guanosine monophosphate second messengers generated by catecholamines, growth hormone, atrial natriuretic peptide, and potentially glucagon (though the physiologic relevance of glucagon *in vivo* is unclear) signal transduction, and are the endocrine stimulators of lipolysis. These regulate reversible phosphorylation that induces conformational changes in perilipins and HSL activation. Insulin signaling induces the opposite set of responses. It is worth noting that, while catecholamines can stimulate lipolysis in adipose tissues and glucose production by the liver, the adipose response is more sensitive. This also applies to the suppressive effects of insulin: adipose is more responsive compared with liver.

In plasma, fat circulates in two forms, as FFAs and as TG contained in lipoproteins; most of this circulating TG during postprandial conditions is contained in very low density lipoproteins (VLDL) and with the addition of chylomicrons during postprandial conditions. Lipoprotein metabolism is addressed comprehensively in Chapter 25. TG catabolism certainly occurs during postabsorptive conditions and can accordingly supply fatty acids for oxidative metabolism, but a large majority of fat oxidation, perhaps as great as 90% during postabsorptive conditions, derives from circulating fatty acids. Brown adipose tissue too contains LDs, and LDs are found in numerous nonadipose tissues, but in aggregate these are minor reserves relative to white adipose tissue, and in general the fatty acids liberated from these LDs are consumed within the tissues in which these are present and not released into circulation, analogous therefore to the situation with muscle glycogen.

KEY POINTS: Lipolysis of Triglyceride Contained in the Adipocyte Lipid Droplet

- In addition to the phospholipid monolayer of lipid droplets (LDs), perilipin proteins are on the surface of LDs and can limit access of lipases to the TG contained in the core of LDs.
- In response to endocrine stimulators of lipolysis (catecholamines, growth hormone, atrial natriuretic peptide), the increase in second messenger cyclic adenosine monophosphate (or cyclic guanosine monophosphate) induces conformation changes in the perilipin coating of LD and makes accessible the protein cofactor for activation of adipose triglyceride lipase, the lipase that cleaves free one fatty acid to generate diacylglycerol.
- Stimulators of lipolysis also activate hormone-sensitive lipase (HSL), which cleaves a fatty acid from diacylglycerol; the activation of HSL and its inactivation by insulin (the sole endocrine suppressor of lipolysis) is a fulcrum of control over rates of lipolysis.
- The remaining fatty acid is cleaved by the action of monoacylglycerol lipase, and this too generates free glycerol. Adipose tissue lacks glycerol kinase, so glycerol liberated by lipolysis cannot be activated to form glycerol-3-phosphate, and thus cannot form a new backbone for TG synthesis. Instead, glycerol freed by lipolysis exits adipose to serve as a gluconeogenic precursor. Glycerol-3-phosphate for TG synthesis is derived from glycolysis in the adipocyte.

Fatty Acid Reesterification as a Component of Flux

There is another aspect of fatty acid flux that is germane to understanding postabsorptive intermediary metabolism, and this is fatty acid reesterification (to TG). Fatty acid esterification, an anabolic process, is the predominant pathway in adipocytes during postprandial conditions (when lipolysis is strongly suppressed), but some partitioning of newly liberated fatty acids to reesterification occurs in adipocytes during postabsorptive conditions, though mostly this takes place in other organs, notably the liver, to which fatty acids are taken up, and fatty acyl-CoAs are partitioned between pathways of esterification and oxidation. Theoretically, following lipolysis of TG, a molar 3:1 ratio of fatty acids to glycerol release from adipose tissue would be anticipated, but the observed ratio is closer to 2 to 2.5:1, denoting an incomplete release of fatty acids. Glycerol newly liberated from TG is released into circulation (and serves as a gluconeogenic precursor in liver), because adipocytes lack glycerol kinase to catalyze the formation of glycerol-3-phosphate (G-3P) from glycerol. Instead, G-3P needs to be generated from the glycolytic intermediate dihydroxyacetone, which in turn depends upon ongoing glucose uptake into adipocytes (which contain scant glycogen and do not carry out gluconeogenesis). When G-3P is available, a portion of newly released fatty acids undergo reesterification into TGs, constituting a futile cycle in this pathway.

After release into circulation, a substantial portion of circulating fatty acids is oxidized, and this fraction is estimated to represent approximately one half (somewhat less) of fatty acid flux under resting postabsorptive conditions. The balance undergoes reesterification; in the liver this contributes to TG packaged into VLDL as well as LD TG.[13] A portion contributes substrate to other pathways of lipid anabolic metabolism, such as phospholipid and sphingolipid synthesis. Considering the "excess" portion of plasma fatty acids, that portion otherwise destined to be partitioned toward reesterification, this portion in the plasma pool can be perceived as an immediately available "reserve" that can quickly "diverted" to meet an arising need for greater fat oxidation, if energy needs dictates, as for instance during the onset of physical activity. This ephemeral plasma pool is more immediately available than allowing for a time lag for mobilization of more fatty acids via an uptick in rates of adipose lipolysis and essentially buys time for this to manifest in increased fatty acid rate of appearance.

Postabsorptive Glucose Production

In a healthy 70-kg human, during postabsorptive conditions, there is at any moment approximately 4 g of glucose in circulation,[19] a reserve representing 16 kcal of available energy (~4 kcal/g glucose). Depletion of just a third of this amount leads to compromised CNS function and morbidity. Thus, the circulating 4 g of glucose is a deceptively thin reserve; consider that this is the glucose content of a "lifesaver" candy. Yet hypoglycemia rarely, if ever, occurs in an otherwise healthy individual, and circulating glucose is replenished continuously by HGP. HGP is governed judiciously, such that the fasting level of plasma glucose is maintained within a tight and stable range, and there are several pathways of metabolism that converge to constitute HGP.[20] In addition to HGP, there is a contribution from the kidneys, estimated to account for 10% to 15% of postabsorptive glucose production,[21] that is further addressed later. Together, the renal and hepatic contribution comprise endogenous glucose production, a term that somewhat erroneously but commonly is used interchangeably with HGP.

During postabsorptive conditions, the rate of HGP is approximately 2 mg/min-kg body weight (or 140 mg/min for the 70-kg human). At the transition into postabsorptive metabolism, if the preceding meals fulfilled daily caloric requirements, hepatic glycogen is in a replete state, at a concentration of approximately 100 g (dry weight glycogen, several fold higher due to the hydrated state of glycogen within tissues). Approximately 50% to 60% of HGP can be attributed to hepatic glycogenolysis as postabsorptive metabolism commences. Glycogenolysis is a tightly governed process, acutely regulated by endocrine signaling that coordinates an opposing reciprocal regulation of glycogen synthesis, so that there is little futile cycling of the glycogen pool. Glucagon and catecholamines, through cAMP, activate PKA, which phosphorylates (and activates) glycogen phosphorylase, while also phosphorylating (and inhibiting) glycogen synthase. Hyperglycemia, through allosteric actions of intracellular glucose in the hepatocyte, can inhibit glycogen phosphorylase. Insulin signaling can directly inhibit glycogenolysis, through an oppositely directed impact on reversible enzyme phosphorylation; thus, the fulcrum of control of glycogenolysis is the opposing actions (and relative concentrations) of glucagon and insulin, and with allosteric modulation by glucose. The action of glucose-6 phosphorylase yields free glucose, which is released into the venous circulation, and the glucose transporter isoform of the liver is GLUT2, a high-Km isoform that enables rapid transmembrane equilibration of glucose concentrations.[6] Together, GLUT2 with the hexokinase isoform of the liver (glucokinase) serve as a "glucose sensor" for the liver. This is also a pairing that acts as a glucose sensor in β cells of the pancreatic islet.

Approximately half of HGP can be ascribed to gluconeogenesis, the synthesis of new glucose molecules, using as substrate principally pyruvate, lactate, and alanine, as well as glycerol derived from lipolysis. The biochemistry of gluconeogenesis is largely a reversal of glycolysis, and the detailed biochemistry of this pathway, futile cycles within glycolysis and gluconeogenesis, and other aspects have been carefully delineated.[22] Control of gluconeogenesis is somewhat complex and entails components attributable to "substrate push" (i.e., availability of the above triose precursors), direct control by insulin, indirect control by insulin (through governing precursor availability), interaction with opposing effects of glucagon on hepatocytes, and longer-term transcriptional control over the expression of enzymes that catalyze gluconeogenesis. There is also support for the concept that insulin signaling in the CNS can exert importance governance over rates of HGP. Because of the importance of dysregulated control of gluconeogenesis to the pathogenesis of hyperglycemia in diabetes mellitus, and due to ongoing debate on the key site(s) of control of gluconeogenesis, the interested reader is provided several excellent references for deeper examination of the issues.[20,23-25] Hepatic oxidation of fatty acids, the principal oxidative substrate for the liver during postabsorptive conditions, provides the energy needed for gluconeogenesis, though fatty acid metabolites (i.e., acetyl-CoA) cannot directly provide substrate for gluconeogenesis. There is evidence that the peripheral action of insulin in inhibiting lipolysis is important in concomitantly controlling rates of gluconeogenesis, both in relation to limiting provision of glycerol as a gluconeogenic substrate and in relation to limiting provision of fatty acid, as an energy source, to the liver. This concept has been termed the "single gateway hypothesis,"[23] linking insulin control of lipolysis as a nexus by which control over gluconeogenesis is exerted. While glucagon has a strong acute effect to stimulate glycogenolysis, it also, through induction of cAMP and PKA activation, has a stimulatory effect on gluconeogenesis, mediated by reversible phosphorylation of enzymes in the pathway of gluconeogenesis. Both insulin and glucagon also mediate effects by influencing transcription control of rate-limiting enzymes in the pathway of gluconeogenesis.

Under usual daily conditions of feeding and fasting, postabsorptive metabolism prevails for 10 to 12 hours, and even this relatively short interval of fasting can result in a meaningful mobilization and depletion of hepatic glycogen (approximately 5 g per hour), especially if there is an interposed session of physical activity. Using the data provided earlier for HGP and fatty acid flux, it can be estimated that the fractional turnover (catalysis) of hepatic glycogen is approximately 0.07% per minute, a relatively small rate of breakdown, but still far greater than the estimated 0.001% per minute fractional turnover of the adipose TG pool. Nonetheless, if glycogenolysis was to proceed at a monotonic rate as postabsorptive metabolism extended, even a liver replete with glycogen would be markedly reduced within 24 hours of fasting. However, hepatic glycogenolysis does not proceed at a fixed, monotonic rate as fasting continues; instead, the proportionality between glycogenolysis and gluconeogenesis (approximately fifty-fifty proportionality at commencement of postabsorptive metabolism) modulates toward a lesser contribution of glycogenolysis and a larger contribution of gluconeogenesis as the duration of postabsorptive metabolism is extended. Regardless, hepatic glycogen is completely depleted within 48 hours of fasting. This adaptive shift, which serves to conserve remaining hepatic glycogen, occurs while largely maintaining the overall rate of endogenous glucose production.

Another aspect of adaptation to a lengthening of the usual period of fasting (e.g., 8–12 hours in a daily cycle) is an increased proportion of endogenous glucose production contributed by renal gluconeogenesis. The contribution of the kidneys to glucose homeostasis has three components: (1) renal gluconeogenesis; (2) renal utilization of glucose, especially in the renal medulla; and (3) renal resorption of filtered glucose, which is approximately 180 g per day in a healthy (nondiabetic) individual.[21] Therefore, it is the last of these, resorption of filtered glucose, that is the largest of the renal effects on glucose homeostasis. However, the focus here will be on renal gluconeogenesis. Like the liver, the kidney expresses glucose-6-phosphatase; these are the only two organs to do so and the only two organs that are capable of gluconeogenesis. Renal gluconeogenesis occurs within proximal tubular cells, which have high energy needs related to ion transport and glucose resorption and a high reliance upon fatty acid oxidation.[26] At the start of postabsorptive metabolism, the renal contribution to endogenous glucose production is estimated to comprise approximately 10% to 15%, all derived from gluconeogenesis. As the duration of fasting extends, especially past 48 hours, which causes complete depletion of hepatic glycogen, the relative contribution of renal gluconeogenesis rises to nearly 40% of endogenous glucoses production,[27] in essence replacing the now exhausted contribution earlier made from hepatic glycogen. To this is added the glucose-sparing effects of ketogenesis and increased rates of lipolysis with fasting. Parenthetically, the last citation is regarded as one of the classic physiologic papers addressing the adaptation of intermediary metabolism to prolonged fasting. Glutamine is an important substrate for renal gluconeogenesis, unlike the liver, which has a greater reliance upon alanine, though both liver and kidney use lactate as a precursor. Another difference is that glucagon is considered to have little effect on renal gluconeogenesis, and instead catecholamines, partly or mostly through influencing availability of substrate precursors, affects rates of renal gluconeogenesis.

KEY POINTS: Postabsorptive Glucose Rates of Appearance

- The rate of appearance for glucose is approximately 2 mg/min-kg body weight.
- 1 mg/min-kg is used by the central nervous system (CNS) and oxidized.
- The remaining half is distributed broadly across peripheral tissues and mostly metabolized only by glycolysis to trioses (pyruvate and lactate), which are recycled to liver as gluconeogenic precursors.
- The size of the blood glucose pool is approximately 4 g, a thin reserve equivalent to the glucose content of a "lifesaver" candy, and the turnover is relatively brisk, with a half-life for glucose of approximately 15 min.

Hormonal Governance of Glucose Production

The opposing actions of insulin and glucagon signaling on hepatocytes are the crucial endocrine regulators of HGP during postabsorptive conditions and have earlier been described with respect to specific pathways involved in HGP. During postabsorptive conditions, the action of insulin serves as a brake upon rates of glucose production, while glucagon serves as an accelerator of glucose production. As earlier noted, glucose utilization during postabsorptive conditions can properly be construed as "insulin-independent," and instead it is the action of insulin in governing HGP that is the way insulin governs rates of postabsorptive glucose flux. Thus, during postabsorptive conditions (and in sharp contrast to postprandial conditions or feeding), the physiological role of insulin is more accurately perceived as restraining or controlling rates of catabolism rather than as a stimulating anabolic influence, checking against excessively high release of stored glycogen and of excessive rates of lipolysis of TG in adipose tissue.

Pancreatic β cells are astute and sensitive glucose sensors, and even slight increases in circulating glucose evoke increased insulin secretion into the portal venous circulation. Conversely, subtle declines of plasma glucose induce corresponding declines of insulin secretion. GLUT2, a high-Km isoform that enables rapid transmembrane equilibration of glucose concentrations, together with glucokinase, serves as a nexus for "glucose sensing" in β cells, though downstream glucose metabolism is essential for triggering insulin secretion. It should also be noted that increased fatty acids can acutely stimulate insulin secretion (though long-term exposure to elevated fatty acids has untoward effects), as can amino acids, so β cells are tightly tuned to intermediary metabolism.[28] Throughout this chapter emphasis is given to how rates of substrate utilization in tissues are governed by underlying energy expenditure, but in this respect the β cell differs in that its rate of substrate uptake and metabolism is largely a function of substrate availability. This "push" aspect of substrate utilization underlies the "gluco-stat" sensing function of the β cell in its governance of intermediary metabolism.

Another important consideration is that approximately 50% of secreted insulin is extracted by the liver.[29] This fraction varies between people and has been estimated to range as high as 80% (though a value nearer 50% is more commonly observed) and to be manifest in part as a heritable factor. Clearly, hepatic first-pass insulin extraction is a key determinant of the amount of exposure of peripheral tissues to insulin at any given level of insulin secretion; the portal to peripheral gradient for insulin concentration is approximately 3:1. A second important consideration is that insulin secretion is pulsatile[30]; the pulses of insulin secretion have a periodicity of approximately 5 to 7 minutes and comprise most of the postabsorptive insulin secretion. It is thought that calcium oscillations, perhaps synchronized with glycolytic oscillations, are a mechanism underlying pulsatile insulin secretion. Although some debate continues, the pulsatile delivery of insulin is regarded as contributing to the effectiveness of insulin action in the liver; in the periphery, these pulses are greatly extinguished.

Characteristically in a metabolically healthy individual, there is a gradient in the insulin responsiveness of adipose, liver, and skeletal muscle, three key insulin-responsive tissues.[31] This cross-tissue gradient of insulin action shapes the pattern of postabsorptive metabolism (as well as governing postprandial metabolism, as will be addressed later). Adipose tissue manifests a high level of responsiveness to insulin, a greater "insulin sensitivity" than liver, as reflected in a left-shifted dose response for suppression of lipolysis relative to suppression of hepatic glucose production. Furthermore, liver is more insulin-sensitive than skeletal muscle, as reflected in a left-shifted dose-response for suppression of hepatic glucose production relative to stimulation of glucose uptake into muscle. Taking this gradient of insulin sensitivity into consideration (adipose > hepatic >> skeletal muscle), together with consideration of the portal delivery and large hepatic extraction of insulin, creating a sharp 3:1 portal to peripheral gradient of insulin concentration, a mechanistic basis can be appreciated, in that adipose and liver are the chief sites of insulin action during postabsorptive conditions, and that skeletal muscle metabolism during postabsorptive conditions is not strongly shaped by insulin action.

Pancreatic α cells are also astute and sensitive glucose sensors, but with opposite patterns of response to β cells, and even slight decreases in circulating glucose evoke proportionate, stepwise increases in glucagon secretion. There is a nearly linear response of increased hepatic glucose production to increases of portal venous glucagon.[32] And because changes in circulating glucose produce reciprocal responses of insulin and glucagon, these opposing changes in hormone concentration, typically quite subtle (at least as measurable in peripheral circulation), nonetheless achieve an amplifying physiological effect on hepatic glucose production.

KEY POINTS: Hepatic glucose production during postabsorptive metabolism:

- The rate of hepatic glucose production (HGP) after an overnight fast is approximately 2 mg/min-kg body weight, about 65% of which is contributed by glycogenolysis and the remaining 35% is contributed by gluconeogenesis.
- Insulin and glucagon are the key endocrine regulators of HGP. In fact, during postabsorptive conditions, the main action of insulin is as a brake upon HGP and lipolysis as glucose utilization is nearly entirely "insulin-independent".
- Glucagon, secreted into the portal circulation like insulin, is a potent stimulator of HGP and a crucial component of the endocrine response that comprises the hypoglycemic counter-regulatory response.
- With an extended period of postabsorptive conditions, the liver adapts to rely more upon gluconeogenesis and less upon glycogenolysis to provision HGP.

Glucose Counterregulation

Across a lifespan of 80 years or more, assuming mostly good general health, an individual will consume 80,000 meals (with corresponding ascents and descents of plasma glucose) and pass through 30,000 postabsorptive periods, yet never experience an episode of symptomatic hypoglycemia. In fact, an occurrence of hypoglycemia, especially during postabsorptive conditions, is never accepted as normal and instead heralds underlying disease, a dangerous adverse drug effect, or other discoverable extenuating circumstances. While the reciprocal actions of insulin and glucagon provide a foundational understanding of this extraordinary protection against hypoglycemia, there is a multifaceted hormonal counterregulatory response that is a vital additional buttress.[33,34] The normative counterregulatory response has been investigated by infusing exogenous insulin, permitting plasma glucose to decline until a symptomatic level of approximately 50 mg/dL is reached, and, after a relatively short interval at this level, halting the insulin infusion is and permitting the plasma glucose to recover. Monitoring of endogenous insulin (via measuring C-peptide levels in blood), glucagon, epinephrine, norepinephrine, cortisol, and growth hormone during the fall and recovery of plasma glucose delineate the counterregulatory hormone response. Based on this paradigm of insulin-induced hypoglycemia, the threshold for near-complete suppression of endogenous insulin secretion is approximately 70 mg/dL, the threshold for robust glucagon secretion is approximately 60 to 65 mg/dL, and that for eliciting epinephrine counterregulation is approximately 60 mg/dL. In response to hypoglycemia, the robust spike of glucagon secretion, much accentuated relative to the more subtle modulations to slight declines of fasting glucose, is only transient in duration, yet achieves prompt robust stimulation of glycogenolysis and a more persistent stimulation of gluconeogenesis. The catecholamine response also acts to increase HGP and accelerate lipolysis. The other key constituents of the counterregulatory hormone response are growth hormone and cortisol, and, relative to glucagon and catecholamines, occur later within the overall counterregulatory hormone response, have a slower onset of effect and a sustained effect. In diabetes mellitus, most especially in type 1 diabetes, there are notable impairments in the counterregulatory hormone response, with impaired glucagon response and, not infrequently, with impaired catecholamine response, and these contribute in a major way to the risk of insulin-induced hypoglycemia, which is one of the major iatrogenic complications of insulin therapy.[35,36]

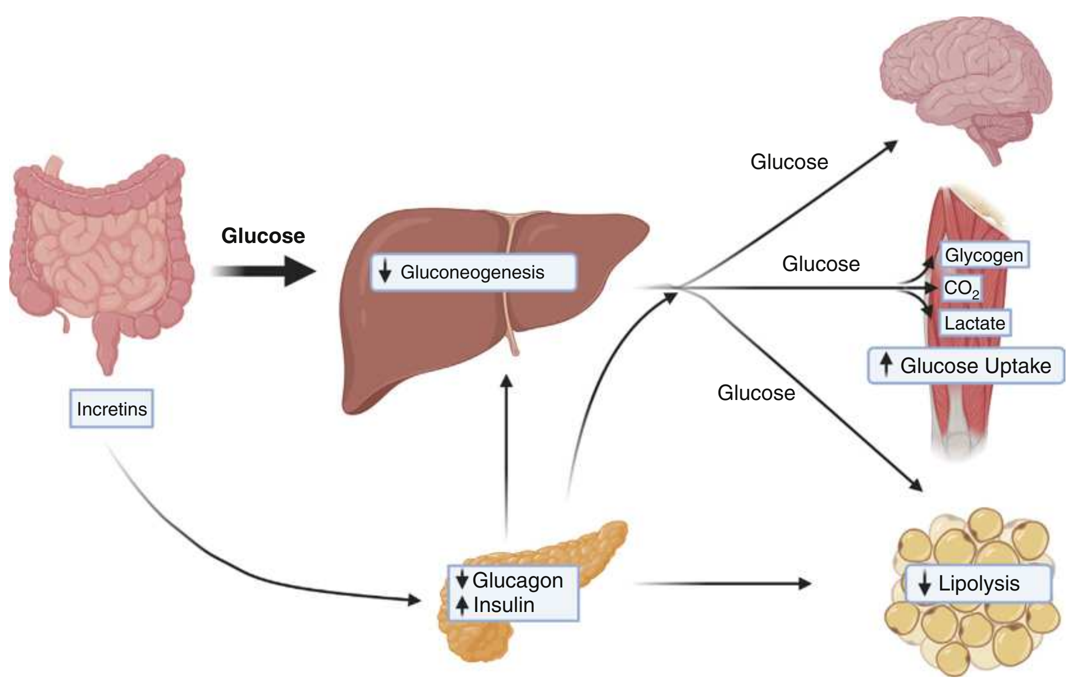

Fig. 22.2 Prandial and postprandial (fed state) metabolism. Glucose and proteins digested and absorbed in the gastrointestinal tract enter the portal venous circulation, enabling first-pass hepatic extraction, while absorbed fat instead enters the circulation via lymphatic entry and in essence undergo first-pass extraction in adipose tissue. One prominent effect of chemosensing of nutrients by enteroendocrine cells is secretion of incretins, which potentiates nutrient-stimulated insulin secretion (and suppression of glucagon secretion). Downstream actions of this pancreatic islet response include suppression of hepatic glucose production, stimulation of hepatic glucose uptake, suppression of lipolysis, and stimulation of glucose uptake into skeletal muscle. Glucose oxidation largely meets bioenergy needs during at least the first half of postprandial metabolism, and glucose availability is such that its storage as glycogen is a prominent pathway in the liver and muscle. *CO_2*, Carbon dioxide.

PRANDIAL AND POSTPRANDIAL INTERMEDIARY METABOLISM

Introduction

Ingestion of food is necessary for survival and brings pleasure (mostly), and there are complex neural circuits, gut hormone circuits, and diverse peripherally generated cues that signal hunger and elicit behaviors to seek food and respond to food ingestion.[37] Knowledge of prandial and postprandial intermediary metabolism is but one aspect of this complex physiology, yet it is foundational for understanding governance of appetite, energy balance, and weight regulation. This knowledge can also inform the dialog as to what comprises a healthy versus an unhealthy diet, though it is of course the longer-term outcomes rather than near-term changes in intermediary metabolism that are truly informative. In terms of definition, the term "prandial" refers to the period of eating, while the term "postprandial" refers to the subsequent period, when digestion and absorption are ongoing and exogenous nutrients are undergoing metabolic disposition in the liver and peripheral tissues. The duration of prandial conditions is approximately 0.5 hour, while postprandial metabolism, depending upon the size and macronutrient composition of the meal, can extend from several to 6 to 8 hours, before a transition is completed back into postabsorptive conditions (or until the next meal is ingested, starting the postprandial process anew).

The main areas of focus of this section will continue to be glucose and fatty acid metabolism within the context of endocrine regulators (Fig. 22.2). Admittedly, this focus on glucose and fatty acid metabolism can be faulted as a "rounding up of the usual suspects"; nontargeted metabolomic surveys indicate at least several thousand components, likely closer to 10,000 discrete small molecule metabolites, and thus comprise a broad spectrum of intermediary metabolism relevant to both postabsorptive and postprandial phases.[38] Considerable progress has been made in identifying biomarkers of metabolic disease and disease risk within the metabolome, one notable example being that of branched-chain amino acids, which cluster with insulin resistance and risk for type 2 diabetes mellitus. Another provocative finding from the metabolome surveys is that fatty acid length and number of double bonds can be a strong predicative risk factor for type 2 diabetes mellitus.[39] However, maturing an understanding of metabolome changes to yield mechanistic insights into the regulation of intermediary metabolism is still a work in progress. The focus here will be upon pathways of glucose and fatty acid metabolism and the context of responses to a prototypical meal, namely one that is a 7- to 10-kcal/kg caloric load (around 40% of daily calorie consumption), comprised of approximately 50% carbohydrate, 30% protein, and 20% fat. Clearly, there is considerable contemporary interest in how variations in macronutrient content and proportions may influence health, modify disease and disease risk, and influence weight regulation. However, an adequate consideration of how dietary variations further influence postprandial intermediary metabolism is beyond the scope of this section. Hopefully, a good grounding in the response to this putative standard meal will enable a balanced and critical appraisal of changes induced by diet modification.

Digestion, Absorption, and Enteroendocrine Cells

The aggregate surface area for absorption in the small intestine is estimated to be approximately 200 m^2, roughly the size of a tennis court, though more recent findings suggest it is only half this surface area.[40] Regardless, it is of a remarkable dimension, especially considering that it is folded in a fully functional capacity within the relatively tight confines of the abdominal cavity. This origami of folding of the surface area reflects the recurring pattern of millions of small intestine villi that amplify the surface area of the lumen, which is further expanded 10-fold by the brush border of the apical surface of enterocytes. A great majority of the cells of the small intestine epithelium are enterocytes, the workhorses of nutrient absorption, and these are supported by the protective action of a smaller population of mucous-secreting goblet cells. However, as a text focused upon endocrinology, it is important to call out the 1% of the gut epithelial population that are enteroendocrine cells (EECs). As a proportion of the cell population of villi, EECs are indeed a miniscule fraction, but in aggregate EECs constitute the largest endocrine organ of the body.

EECs are chemical sensors of nutrients and, in response to carbohydrate, lipid, protein, and other components of intestinal chyme, release peptide hormones and neurotransmitters.[41] What is conceptually unique about EECs relative to other endocrine glands is that, whereas the latter sense and respond to the internal milieu to maintain homeostasis, EECs respond to the external challenge presented by ingested food to prepare the gastrointestinal system for digestion and absorption, prepare peripheral tissues for metabolism of food, prepare pancreatic islets for insulin and glucagon responses, and carry out gut–brain signaling governing satiety.[42] Thus, the EECs are a complex endocrine system that is central in governing postprandial intermediary metabolism.

EECs are a highly diverse cell population. Formerly it was thought that there was one EEC cell type for each gut hormone, but recent advances in single-cell transcriptomics and other approaches now clearly demonstrate that an individual EEC can secrete several gut hormones in a coordinated and consistent manner, and that EEC subsets are distributed in an orchestrated anatomic pattern; the functional ramification of all this remains to be more fully comprehended. Several of the gut hormones secreted by EECs govern the satiety response to eating, including glucagon-like peptide-1 (GLP-1), peptide tyrosine tyrosine, and cholecystokinin, while ghrelin signals hunger. Some of these and other various gut hormones have a key role in regulating gut motility, bile acid release, pancreatic exocrine secretion, and intestinal water and electrolyte secretion. Here, we will focus upon the component of EEC response characterized as the incretin axis, and this is presented subsequently in connection with insulin and glucagon responses to meal ingestion.

Returning to the issues of digestion and absorption of food, the essential chemical reaction that renders food into its constituent components so that these are in a state that can be absorbed by small intestine enterocytes is hydrolysis. Hydrolysis cleaves starches and smaller carbohydrate polymers, cleaves acyl groups from the glycerol backbone of TGs (and from cholesterol esters), and breaks up ingested protein by cleaving amide linkages between amino acids. An array of enzymes, many secreted and others residing on the brush border surface of enterocytes, catalyze hydrolysis of ingested macromolecule nutrients. For the interested reader, more detailed information on the digestive and absorptive process is referenced.[43] The process is facilitated by and dependent upon bulk secretion of water and electrolytes that modulate pH and disperse nutrients within the gut lumen and by bile that emulsifies fat. Amylase is secreted by the exocrine pancreas in sufficient quantity to rapidly hydrolyze starch into disaccharides that are then efficiently cleaved by brush border enzymes into sugar monomers; mostly it is the monomer glucose that is absorbed and quickly released into the portal venous circulation. This abundant enzymatic capacity enables rapid entry of carbohydrate into circulation, a rate determinant being more gastric emptying than hydrolytic enzyme capacity for carbohydrate. A considerable proportion of glucose absorption is mediated by coupling with sodium absorption through the sodium-glucose transporter-1, and there is also contribution from GLUT2. Pepsin, secreted within the stomach and with optimal activity in the acidic environment of the stomach, dissembles collagen within proteins, providing pancreatic peptidases in the small intestine with more ready access to cleave protein into smaller fragments that are ultimately rendered to individual amino acids by enterocyte brush border peptidases. Amino acids, mostly similar to glucose but with some exceptions, appear relatively quickly in the portal circulation.

The situation with digestion and absorption of fat differs in several respects from that of carbohydrate and protein, nutrients that are more polar than fat and more water-soluble, and this physiology of intestinal lipid metabolism has recently been reviewed.[44] Briefly, the strong hydrophobicity of TG, the major component of ingested fat, is an impediment to its digestion. This hydrophobicity limits the surface area of fat globules and thus constrains access of pancreatic lipase and cholesterol esterase. Emulsification of fat by bile helps to form small lipid micelles, vastly expanding the surface area on which lipase can act. Parenthetically, bile acids are now recognized to have an important signaling role, clearly akin to motifs of endocrine signaling, and are the ligands for receptor-mediated actions in liver and peripheral tissues.[45] Accordingly, it is appropriate to include bile acid signaling as part of the multifaceted panoply of gut-derived messages that govern intermediary metabolism, intestinal physiology, systemic energy balance, and appetitive behavior.

Fatty acids and monoacyl-glycerol are absorbed into enterocytes, where long-chain acyl group are reesterified, and the newly formed TG is packaged with apoB48 into large chylomicron particles. Chylomicrons enter lacteals contained within small intestine villi and enter systemic circulation via the lymphatic thoracic duct, thereby foregoing first-pass hepatic extraction, unlike glucose and amino acids. Interestingly, large chylomicrons released by enterocytes have too large a diameter to permit passage through the fenestrations within hepatic capillaries, and, as will be addressed later, it is as chylomicron remnants, reduced in size by catabolism in peripheral tissues and notably adipose, that such passage becomes possible.

Another difference from carbohydrate and protein absorption is that TG entry into systemic circulation is significantly delayed, enough that ingested glucose and fat entries may, at least figuratively, be considered somewhat separate phases. It can be speculated that this temporal separation, together with the different ports of entry (portal vs. systemic) may act to diminish the fatty acid competition in the early prandial period that is predominated by glucose metabolism, and that later, with relatively prompt clearance of ingested glucose, the potential for glucose competition during metabolism of ingested fat. The notion of glucose–fatty acid substrate competition as a governing principle of intermediary metabolism is further addressed subsequently.

KEY POINTS: Digestion and Absorption of Nutrients

- The surface area of the small intestine is 100-fold greater than that of the body's skin (250 vs. 2 m^2), but food must be cleaved by hydrolysis into monomeric constituents to be absorbed by enterocytes.
- The more polar, water-soluble nutrients of glucose and amino acids are absorbed into enterocytes and released at their basal surface into the portal venous circulation for first-pass uptake and metabolism by the liver.
- The less polar, hydrophobic lipid nutrients are absorbed into enterocytes after emulsification with bile, after which lipase cleaves triglyceride (TG) to fatty acids and monoacylglycerol (MAG). On entering enterocytes, fatty acids and MAG undergo reesterification to form TG, and this is packaged into large chylomicrons.
- Chylomicrons are released into lacteals of the intestinal villi and enter systemic circulation at the level of the thoracic lymph duct, thus initially bypassing the liver, unlike carbohydrate and protein.

Insulin and Glucagon Responses

It is difficult to overstate the importance of insulin as a determinant of the metabolic response to feeding and in evoking the metabolic shift from fasting patterns of metabolism. Insulin secretion increases promptly upon eating, and by approximately 5- to 10-fold during prandial versus fasting conditions, dependent upon meal size and carbohydrate content. The sharp rise in insulin secretion has a mirror image in the suppression of glucagon secretion, the latter reflecting a regulatory role of the sharp rise in insulin to reduce glucagon secretion.

Certainly, the vigorous insulin secretion is in response to a rise in plasma glucose, and with potentiation by other nutrients (e.g., amino acids). Yet, a century ago, perceptive investigators postulated an additional impetus, at the time speculatively termed the incretin effect, the components of which were later identified.[46] One way to capsulize the effect of the incretin effect is to recount a crucial experimental finding: when a postprandial (peripheral) glucose concentration was simulated by a carefully modulated infusion of glucose, the insulin secretory response was clearly lower, by more than half, than when equivalent hyperglycemia occurred naturally in response to ingestion of glucose. This difference in the amount of insulin secreted suggested the action of a signal(s) additional to hyperglycemia itself; the components of the incretin axis were later identified as the incretin hormones (incretins) glucose-dependent insulinotropic polypeptide (GIP) and GLP-1. As noted earlier, GIP and GLP-1 are secreted by EECs. The EECs secreting GIP are predominately located in the small intestine, while EECs capable of secreting GLP-1 have a more extensive distribution in both the small and large intestines. In addition, there can be cosecretion of other gut hormones in conjunction with that of GIP and GLP-1. These EECs function as nutrient chemoreceptors responsive to ingested glucose, fatty acids and fatty acid metabolites, and amino acids. The secretion of GIP and GLP-1 is further modulated by G protein–coupled receptors (GPCRs) expressed on GIP- and GLP-1–secreting EECs. Prominent among these GPCRs are a family of lipid-sensing receptors (i.e., GPR40, GPR120, GPR119, and others) that respond to fatty acids of differing chain length and to fatty acid metabolites, the generation of which can also derive from metabolic activity in adjacent enterocytes, signifying operation of paracrine signaling.[47] In turn, many of these lipid-sensing receptors are also expressed on pancreatic β cells (and, for some, on pancreatic α cells). The receptors for GIP and GLP-1 are expressed on pancreatic β cells and α cells. Increases in GIP and GLP-1 secretion occur as early as 5 to 10 minutes after the start of eating and continue for most of the prandial period, and secretion of GIP is more sustained into the postprandial period. As alluded to earlier, GIP and GLP-1 strongly potentiate glucose-induced insulin secretion, which is also to state there is only a nominal effect to stimulate insulin secretion at euglycemia or hypoglycemia. There are emerging findings that GIP may amplify the glucagon response to hypoglycemia,[48] and that the GPCR GPR119 has a similar effect.[49] These latter findings raise the provocative notion that there is an aspect of incretin biology that helps to defend against hypoglycemia, perhaps acting in a physiological context in the descending arm of plasma glucose during postprandial metabolism by heightening the sensitivity of an α cell response.

It has been estimated that, in healthy individuals, the actions of these incretin hormone account for more than half of the prandial increase in insulin secretion. GLP-1 also has receptors in the CNS and a role in governing satiety and appetite; whether GIP has a similar role is less clear. GLP-1 also has effects on gut motility. It suffices to state that the incretin axis, and more broadly the EEC-derived hormones, have a major role in the overall endocrine governance of postprandial metabolism.

KEY POINTS: Entero-endocrine Cells and the Incretin Response

- Enteroendocrine cells (EECs) are distributed throughout the stomach, small intestine, and large intestine in a regulated distribution of pluripotential hormone secreting cells that act as chemosensors of nutrients and nutrient metabolites.
- EECs comprise just 1% of the epithelial cell population of the small intestine, but in aggregate constitute the largest endocrine organ in the body.
- One aspect of the EECs constitutes the incretin axis, composed of two gut hormones, glucose-dependent insulinotropic polypeptide (GIP) and glucagon-like polypeptide-1 (GLP-1), that are secreted in response to meal ingestion.
- In a glucose-dependent manner, GIP and GLP-1 robustly amplify glucose-dependent insulin secretion, likely accounting for 50% of the meal-related increase in insulin secretion. The incretin effects are minor at fasting glucose levels due to low secretion of GIP and GLP-1 and because of their glucose-dependent action on insulin secretion.
- A number of lipid-sensing G protein–coupled receptors modulate GIP and GLP-1 secretion and can also modulate insulin secretion directly via receptor expression on β cells.

Effects on Energy Expenditure and Respiratory Quotient

During prandial conditions, extending into the postprandial period, there is a modest increase in systemic energy expenditure. This is termed the thermic effect of food and in aggregate comprises approximately 10% of daily energy expenditure. The processes of ingestion, digestion, and absorption, as well as downstream metabolism of nutrients, are considered to account for the increase in energy expenditure that comprises the thermic effect. The magnitude of this effect is partially dependent on the type of nutrient consumed, being less for carbohydrate than for protein or fat.

In addition to the thermic effect of food ingestion, there is characteristically a robust effect of meal consumption on the RQ, the quotient of CO_2 production to O_2 consumption, described earlier, and a parameter reflecting relative contributions of carbohydrate versus fat combustion. And, as earlier noted, a typical fasting RQ in a lean, healthy individual is approximately 0.80 ± 0.03, and this can characteristically increase to a value approaching or achieving 1.0 (signifying complete reliance upon glucose oxidation) within an hour of eating, especially if carbohydrate comprise 50% or more of the calories consumed.[7] This indicates that, in the early postprandial period, glucose oxidation nearly completely accounts for energy expenditure. As the postprandial period continues, the RQ value gradually recedes toward a resumption of postabsorptive values. Peak rates of glucose oxidation after a meal approach 3 mg/kg-min, or nearly 50% of the peak rate of systemic glucose appearance (~6–8 mg/kg-min) following meal ingestion, which in turn is a 3- to 4-fold elevation compared with fasting HGP rates (2 mg/kg-min).[50,51] In aggregate, across the prandial and postprandial periods, it has been estimated that oxidation of glucose accounts for 40% to 50% of the metabolic disposition of ingested glucose, with the remainder partitioned to "non-oxidative" metabolism, largely glycogen storage in liver and muscle, together with a smaller fraction that is metabolized glycolytically but not oxidized.

Hepatic Glucose Metabolism

In response to the ingestion of a mixed meal or a predominately glucose load, the liver promptly switches from its role during fasting as the primary producer of glucose to one of robust glucose uptake, accruing glycogen while concomitantly suppressing release of glucose. The activation of robust glucose uptake by the liver requires a combination of both hyperinsulinemia and hyperglycemia.[20,52] Experimentally raising insulin while maintaining euglycemic levels of plasma glucose (i.e., 80–100 mg/dL) does not substantially increase glucose uptake by the liver, though these conditions do suppress hepatic glucose production. Similarly, hyperglycemia by itself (e.g., experimentally controlling insulin concentration through concomitant somatostatin and exogenous insulin infusion) does not elicit strong glucose uptake by the liver, though this suppresses hepatic glycogenolysis. Yet, the combination of hyperinsulinemia and hyperglycemia is a strong stimulus for hepatic glucose uptake. It is important in this context to note that, during the absorptive phase of a meal, portal concentrations of glucose exceed those in the periphery, and this acts to potentiate the effect of the portal to peripheral gradient for insulin in stimulating hepatic glucose uptake. It has been further postulated that a portal to arterial glucose gradient generates a portal signal amplifying hepatic uptake of glucose; the exact nature of the putative portal signal has not been firmly identified.[53]

Following a 12-hour or longer postabsorptive phase, a single meal does not fully replenish hepatic glycogen, but, incrementally, over the course of two to three meals in a day, hepatic glycogen becomes fully replete, with a content of approximately 70 to 100 grams, dry weight (Table 22.1). Both increased intracellular glucose availability and insulin signaling activate the enzyme glycogen synthase in hepatocytes while reciprocally inhibiting glycogen phosphorylase; both enzymes are governed by phosphorylation and dephosphorylation cascades previously described. Because the hepatocyte glucose transporter, GLUT2, enables rapid exchange of glucose across the full range of glucose concentrations, glucose transport is not a rate-limiting step *per se* for rates of glycogen synthesis in the liver, but rather metabolic control is attributed to downstream steps, notably glucokinase and glycogen synthesis. This differs from skeletal muscle, as will be addressed later.

Overall, it is estimated that glucose uptake by the liver accounts for approximately one third of the disposition of ingested glucose. This alone is a sizeable contribution, but by itself is still an underestimation of how the prandial transitions of hepatic glucose metabolism shape glucose tolerance. Suppression of hepatic glucose production during prandial and postprandial conditions is the additional crucial determinant of glucose tolerance and indirectly governs disposition of the portion of ingested glucose that is not taken up by the liver and instead enters the peripheral circulation. Suppression of HGP occurs promptly during the prandial and postprandial phases; HGP reaches a nadir within an hour of eating, and there is a gradual return to fasting rates of HGP over 4 to 6 hours following meal ingestion.[50,51] Regarding governance of HGP suppression, hyperinsulinemia has a strong effect to suppress glycogenolysis, as noted earlier. Interestingly, gluconeogenesis is reduced but not nearly as completely suppressed as glycogenolysis. However, the output of newly synthesized glucose is redirected toward glycogen synthesis rather than as release from the hepatocyte into circulation. This contribution to glycogen synthesis, derived from glucose created by gluconeogenesis, is termed the "indirect pathway" of glycogen formation to distinguish it from the direct pathway based on hepatic glucose uptake and direct incorporation of glucose-6-phosphate into the glycogen synthesis pathway. The indirect pathway of glycogen formation is a meaningful component of glycogen repletion during postprandial conditions.

Postprandial Peripheral and Central Nervous System Glucose Utilization

The patterns of peripheral tissue utilization of glucose divide into those that are insulin-independent and those that are insulin-dependent. CNS consumption of glucose, as described earlier, is insulin-independent and continues unchecked during fed conditions, and, with a low-Km glucose transporter (i.e., GLUT3), this rate does not increase due to hyperglycemia. Nonetheless, the CNS does make an important contribution to the disposition of ingested glucose, accounting for an estimated 25% or more of the ingested amount. This partitioning of ingested glucose to the CNS is an "indirect effect" consequent to, and dependent upon, suppression of HGP and the replacement of circulating glucose with that absorbed from the meal. This principle of ingested glucose substituting for reduced HGP pertains to other tissues in accounting for a relatively rapid distribution and uptake of ingested glucose.

There is also a potentiating effect on glucose utilization caused by a reduced availability of plasma fatty acids. With the sharp increase in insulin during feeding, there is robust suppression of lipolysis in adipose tissue and a consequent sharp reduction in plasma fatty acids. Though ingested fat packaged into chylomicron delivers fatty acids to peripheral tissue (as will be discussed later), the temporal delay in entry of chylomicrons relative to ingested glucose creates a situation such that, in the early phase of postprandial metabolism (for approximately the first 2 hours), glucose is the more predominately available substrate. Thus, the many tissue and organs that have capacity to take up and utilize fatty acids have diminished access to these, and alternatively rely more fully upon circulating glucose. The increased glucose flux during postprandial conditions is associated with a postprandial rise in circulating lactate levels, an approximate doubling, which provides gluconeogenic substrate for the indirect pathway of hepatic glycogen synthesis described above.

In the preceding section on postabsorptive metabolism, skeletal muscle was highlighted as an exemplar of fatty acid uptake and oxidation and equally, but oppositely, during postprandial metabolism, skeletal muscle is an exemplar of insulin-dependent glucose uptake. Glucose transport across the sarcolemma is regarded as the rate-limiting step for insulin-stimulated glucose utilization by muscle[54,55]; physiological levels of hyperinsulinemia increase the kinetics of glucose transport in muscle by an order of magnitude compared with postabsorptive conditions. The postprandial increase in plasma insulin is sufficient to initiate the signal transduction cascade that greatly increases glucose transport capacity, and this stems from the molecular physiology of GLUT4, the glucose transporter predominant in skeletal muscle. Under postabsorptive conditions, GLUT4 is mostly contained within cytosolic vesicles, sequestered away from the sarcolemma. The insulin signaling cascade triggers translocation of GLUT4 to insertion within the sarcolemma, where it can manifest functionality to enable bidirectional facilitated transport of glucose.[6] Across a limb, the postprandial fractional extraction of glucose increases nearly 20-fold or more compared with postabsorptive conditions. Also, under resting conditions, not all capillaries in skeletal muscle are patent and receive equal perfusion: a sizeable fraction is closed at any instance during resting conditions, and in response to increased insulin a process of capillary recruitment and increased perfusion occurs.[56] Taken together, the enhanced delivery and distribution of insulin and glucose into the interstitial space of skeletal muscle potentiate glucose transport, the rate-limiting step for glucose metabolism in muscle. It is estimated that skeletal muscle accounts for the disposition of approximately one third of ingested glucose during postprandial conditions. Thus, the trilogy of brain, liver, and muscle accounts for much of the disposition, approximately 90%, of ingested glucose.

It is estimated that glycogen formation is the metabolic fate that accounts for approximately half of postprandial glucose uptake into muscle.[50,57] The role of insulin signaling in myocytes largely parallels that outlined for hepatocytes in activating glycogen synthesis, albeit without contribution from the indirect pathway utilizing gluconeogenesis that does not occur in muscle. Glucose oxidation accounts for approximately 40% of insulin-stimulated glucose uptake, and the remainder, less than 10%, is released from muscle as pyruvate, lactate, or alanine, thus continuing or increasing the Cori cycle. Like the rise in systemic RQ during feeding, in skeletal muscle regional indirect calorimetry reveals a sharp rise in RQ, and it is the rise in muscle RQ that in good measure underlies the rise of systemic RQ.[50] Cardiac muscle during postprandial conditions manifests a metabolic response similar as that of skeletal muscle, increasing glucose uptake and oxidation and increasing glycogen formation, while reducing reliance upon fatty acid oxidation.

The decrease in fat oxidation is also mediated by a suppression of lipolysis and reduced availability of plasma fatty acid, and intracellularly by generation of malonyl CoA from increased glycolytic flux, thus inhibiting CPT-1, crucial for translocation of acyl-CoA into mitochondria. The importance of substrate competition in governing glucose versus fatty acid metabolism, an important concept of intermediary metabolism, was initially articulated by Randle.[58] This substrate competition can be empirically demonstrated in humans as well as in *in vitro* laboratory studies. Experimentally maintaining fasting levels of plasma fatty acids (by lipid infusion) even while raising insulin into the upper physiological range impairs insulin-stimulated glucose uptake into muscle and lessens suppression of HGP.[9,59] In fact, the acutely induced pattern of insulin resistance caused by fatty acids under these experimental conditions bears a strong resemblance to that observed in obesity and type 2 diabetes mellitus and has been a strong impetus for deeper inquiry into the "lipotoxic" contributions to insulin resistance and disease pathogenesis.[60] Indeed, in a provocative and classic essay it was argued that, if not for the ease of the water-soluble chemistry of glucose relative to the complexity of lipid analyses, emphasis may not have been placed so strongly on perturbed glucose metabolism in studying diabetes, and instead more focus may have been allocated to perturbation of fatty acid metabolism in the pathogenesis of diabetes.[61]

The shift from a reliance upon fat oxidation during postabsorptive conditions to strong reliance upon glucose oxidation during postprandial conditions has been termed "metabolic flexibility,"[8,62] and is a prominent aspect or manifestation of healthy metabolic transition, especially for postabsorptive to postprandial transitions. Earlier, the substrate signaling role of malonyl-CoA was addressed in mediating the transition from fatty acid to glucose oxidation.[63] Further, hyperglycemia itself, independent of a concomitant rise in insulin, can evoke a rise in carbohydrate oxidation and a corresponding reduction in fat oxidation, systemically and within skeletal muscle.[64,65] Thus, the concept of substrate competition is bidirectional, with fatty acids impeding insulin-stimulated glucose metabolism and hyperglycemia perturbing postabsorptive patterns of fatty metabolism. This is an important concept within regulation of intermediary metabolism and is relevant to metabolic diseases like type 2 diabetes mellitus.

KEY POINTS: Postabsorptive Metabolism

- The relative stability and constancy of plasma glucose and fatty acid concentrations derives from tightly governed rates of appearance, mobilized from endogenous sources and rates of disappearance from plasma into tissues.
- Endocrine–substrate feedback loops are a primary mechanism for control of glucose and fatty acid rates of appearance, whereas rates of glucose and fatty acid utilization are concentration-driven and governed by energy requirements.
- There is a relative parity in oxidation of fatty acids and glucose during postabsorptive metabolism, the latter occurring mainly in the CNS, but the former broadly distributed across peripheral tissues.

Postprandial Adipose Tissue Metabolism

Glucose uptake into adipose tissues increases during postprandial conditions of hyperglycemia and elevated insulin. Like skeletal muscle, adipose tissue expresses the GLUT4 transporter isoform that undergoes translocation to the cell surface under insulin stimulation. However, it has been challenging to quantify rates of glucose uptake into adipose tissue, at least with the same clarity that has been achieved for skeletal muscle; arteriovenous balance studies are technically difficult due to the small vessel diameters in adipose, microdialysis has provided good insight, and, more recently, metabolic imaging approaches have yielded quantitative estimates.[66,67] The emerging consensus appears to be that adipose tissue may account for approximately 5% to 10% of glucose utilization during postprandial conditions. However, adipose tissue has a relatively low rate of oxygen consumption and contains minor amounts of glycogen, and the chief metabolic fate of glucose taken up by adipose is glycolysis, with the generation of G-3P to serve as a backbone for TG synthesis. Insulin-stimulated glucose uptake into adipose can properly be regarded as providing a requisite foundation for the crucial role of adipose in postprandial disposition of ingested TG. There is also efflux of lactate from adipose into venous circulation, which continues during postprandial metabolism, indeed at rates that exceed postabsorptive conditions. Special notation should be made of brown adipose tissue (BAT) and its capacity for substrate utilization, which considerably exceeds that of white adipose tissue when considered on a per cell or per unit weight basis. Indeed, while skepticism had once seemed to prevail about the existence of meaningful amounts of BAT depots in humans, metabolic imaging with glucose analogs convincingly demonstrated both the existence and heightened metabolic rates of BAT.[68] The postprandial response of BAT is a contributor to the aggregate thermic effect of food in keeping with the uncoupling of BAT mitochondria and this tissue's thermogenic function.

During the postprandial phase there is strong insulin-induced suppression of lipolysis and a shift toward TG storage. The drop in plasma fatty acids and glycerol is evident promptly in response to feeding, reaches a nadir at approximately 1 hour after the start of eating, and persists, only gradually returning to usual postabsorptive levels over the duration of the postprandial period. This is a pattern that parallels that for suppression of HGP and is evocative of the single-gateway hypothesis of insulin governance of lipolysis and HGP that was cited earlier. However, quantitatively, the most important aspect of adipose metabolism following meal ingestion concerns lipoprotein metabolism. Following fat ingestion, chylomicrons enter systemic circulation (via lymphatic drainage from splanchnic tissues), beginning to appear an hour or so after the meal, reaching a peak several hours after meal ingestion and remaining elevated for up to 6 to 8 hours if the amount of fat ingestion was relatively large. Chylomicrons are too large to exit capillaries, yet adipose tissue has a major role in the metabolism of chylomicrons, through its expression, synthesis, and release of lipoprotein lipase (LpL).[12] LpL released from adipocytes binds to the luminal surface of adjacent capillaries. The release of LpL from adipocytes is stimulated by insulin, and accordingly recedes during postabsorptive conditions. Thus, the molecular physiology of insulin action in adipose tissue may be construed as establishing a "first-pass" capacity for the partitioning of ingested fat toward this tissue by its catabolic effect on chylomicron TG. The armatures of LpL enable engagement with chylomicrons and catalyze hydrolysis of TGs into fatty acids that can be taken up by adipocytes, where, in conjunction with G-3P generated by glycolysis metabolism, provide substrate for esterification into TG and storage in the adipocyte LD.

Though there is a potential for spillover into systemic circulation of fatty acids liberated by LpL, the amount is relatively minor, denoting an efficient capacity for fatty acid uptake in insulin-stimulated adipocytes. Nonetheless, catabolism of chylomicrons is only partially completed during a passage through adipose capillaries, and the resulting remnant chylomicrons, now of diminished diameter and with a change in composition (decreased ratio of TG to phospholipid), are further acted upon in the liver (as discussed later) and in subsequent passages through adipose and other tissues. Skeletal muscle, heart, and other tissues express LpL. However, in skeletal muscle, LpL activity generally decreases in response to increased insulin and is higher during fasting conditions, thus directed toward VLDL rather than chylomicron catabolism.

KEY POINTS: Tissue Distribution of Ingested Glucose During Postprandial Metabolism

- The combination of hyperglycemia and hyperinsulinemia, accentuated within portal circulation relative to the peripheral circulation, triggers a shift in the liver from glucose export to robust glucose uptake, with a predominant metabolic fate being repletion of hepatic glycogen. Liver accounts for approximately one third of the disposition of ingested glucose.
- The strong, rapid, and sustained suppression of HGP after meal ingestion effectively substitutes ingested glucose for that of endogenous glucose as the source for CNS glucose oxidation, accounting for approximately one quarter of the disposition of ingested glucose.
- The prandial rise in insulin signals recruitment of GLUT4 to the cell surface in muscle and adipose. Glucose uptake by muscle accounts for a third or more of ingested glucose disposition, and the metabolic fate of this is directed toward glycogen formation in muscle and a marked shift from fat to glucose oxidation.
- Adipose glucose uptake may account for a tenth of glucose uptake during postprandial conditions and has a key role in providing generation of glycerol-3-phosphate to provide the backbone for triglyceride formation.
- Overall, roughly half of glucose metabolism during postprandial conditions is consumed in glucose oxidation, and the remainder is stored as glycogen, including a large portion of the gluconeogenic flux occurring in liver, the indirect pathway for glycogen synthesis.

Hepatic Metabolism of Fatty Acids and Lipoproteins

In considering the contributions of various organs and tissues to postprandial metabolism, we began with outlining hepatic glucose uptake and glycogen repletion, and, in beginning to conclude this section, a turn to another aspect of the postprandial hepatic response is warranted. The liver is the main metabolic "clearing house," and hepatic metabolism of remnant chylomicrons is an important aspect of postprandial intermediary metabolism and lipoprotein metabolism, one that is crucial for removing chylomicron remnants and restoring the predominance of VLDL particles as TG-rich lipoproteins during postabsorptive conditions. As noted earlier, newly formed chylomicrons are too large to traverse the 100-nm fenestrations of hepatic capillaries, but, in a reduced size after partial hydrolysis by adipose LpL, remnant chylomicrons (now approximately 75 nm in diameter) can be metabolized in the liver and undergo receptor-mediated uptake into hepatocytes for degradation. Some of the lipid components are recycled into newly formed VLDL, and a proportion enter other lipid metabolism pathways, including sphingolipid and phospholipid pathways and TG storage in hepatic LDs, and a portion undergo oxidation. Thus, there is a complex map of potential lipid metabolism pathways that operate in hepatocytes and that are important in completing the transition from postprandial to postabsorptive metabolism.[12]

The role of the liver in ketogenesis was addressed in the section on postabsorptive metabolism, as well as how ketogenesis increases as fasting is extended in duration. Conversely, during postprandial hepatic metabolism the pathway of *de novo* lipogenesis (DNL) can increase if the carbohydrate load is large and is consumed in conjunction with high caloric intake.[69] Attention has increasingly turned to the role of DNL in the pathogenesis of hepatic steatosis associated with obesity and insulin resistance, termed nonalcoholic fatty liver disease. When there is a surfeit of pyruvate-derived acetyl-CoA, sufficient to drive formation of mitochondrial citrate and its export from the mitochondria to the cytosol, then the enzyme acetyl-CoA carboxylase, under the influence of hyperinsulinemia, catalyzes the formation of malonyl-CoA. An important role for malonyl-CoA as an allosteric inhibitor of CPT-1 and fatty acid translocation into the mitochondria has been described earlier. In addition, the enzyme fatty acid synthase carries out DNL by repetitively using malonyl-CoA to construct fatty acids, most commonly C-16 palmitate. Yet another important contribution of malonyl-CoA is to provide substrate for fatty acid elongation to form very long chain fatty acids (i.e., chain length >22 carbons). Very long chain fatty acids serve specialized functions in membrane formation, and long chain fatty acids, particularly polyunsaturated fatty acids, can have a signaling function in transcriptional control of hepatic lipid metabolism.

Methodologic Approaches to Investigating Postprandial Conditions

Methods for assessing postabsorptive metabolism, notably isotope dilution flux studies and indirect calorimetry, were discussed in a previous section, and here attention is turned to investigations of postprandial intermediary metabolism. Descriptive studies are highly informative and of practical clinical utility, and are commonly done with measurements of metabolites and hormones following glucose challenges and mixed-composition meal ingestion. Flux studies of glucose metabolism can be integrated into these by including labeled glucose in the ingested load (to trace its entry into peripheral circulation and estimate its uptake in the splanchnic tissues, notably liver), while concomitantly infusing a separately labeled glucose isotope to enable determination of HGP and overall glucose rate of disappearance. Several citations that utilize this approach have been provided.[50,51] Also, indirect calorimetry can reveal patterns and rates of fatty acid and glucose oxidation. Measurements of arteriovenous differences provide further insights into the contributions of various tissue beds, notably for skeletal muscle, and with some application to the splanchnic bed and adipose tissues. However, there remains a main limitation to these approaches regarding measuring insulin sensitivity. The pronounced dynamic changes in glucose, fatty acids, and insulin concentrations, together with interindividual differences in respective levels, makes it quite challenging to "isolate" how efficiently (or inefficiently) insulin stimulates metabolism. Mathematical modeling approaches that have used the data from an oral glucose challenge or mixed meal challenge and consider insulin secretory rates have derived estimations of insulin action.[70] From these parameters a disposition index can be determined that capsulizes the integrated efficiency of glucose disposition.

A paradigm shift in quantifying response to insulin was the development of an experimental platform widely termed the "glucose clamp." Initially designed by Andres and colleagues,[71] and later refined, modified, and evolved by countless investigators, the core concept is to attempt to hold fixed (i.e., steady state) concentrations of insulin and plasma glucose, achieved by constant infusion of insulin and an adjustable infusion of glucose, adjusting the rate of glucose infusion based on frequent measurements of plasma glucose to hold steady or "clamped" blood glucose concentrations.[72] The key outcome is the steady-state rate of glucose infusion, which, in the context of stable insulin and glucose concentrations, provides a quantitative index of insulin sensitivity in stimulating glucose utilization. This allows comparison across individuals and groups of a parameter of insulin action. This platform can also employ isotope labelled glucose infusion to estimate the effect of insulin on HGP, can employ indirect calorimetry to study oxidative metabolism, and study effect on lipolysis and fatty acid metabolism, as well as other parameters. So, in many respects, a glucose clamp recapitulates a metabolic context analogous to postprandial conditions, but of course is not a full recapitulation, because it experimentally fixes glucose and insulin concentrations rather than allowing the dynamic changes that characterize postprandial intermediary metabolism. Moreover, the peripheral infusion of insulin (and of glucose) does not recreate the portal to peripheral gradients that are crucial factors in shaping postprandial hepatic metabolism.

Perhaps the greatest utility of the glucose clamp approach has been to enable studies of insulin-stimulated skeletal muscle metabolism. Under the conditions of hyperinsulinemia, and while maintaining euglycemia with the clamp method, skeletal muscle accounts for nearly 70% to 80% of overall glucose utilization. Also, the metabolic fate of glucose utilization during euglycemia clamp conditions fairly closely mirrors that observed under postprandial conditions: half of more of glucose taken up is stored as glycogen, a large fraction is immediately oxidized, and a smaller fraction undergoes glycolysis and release as lactate and related trioses. Arteriovenous limb balance studies can provide additional clarity or specificity regarding skeletal muscle metabolism.[9,57] Another methodological advance has been to use the glucose clamp as a physiologic platform upon which concomitant imaging can be done. One prominent example has been to use magnetic resonance spectroscopy to image the accretion of glycogen in skeletal muscle or liver.[73] Another approach, cited earlier, has been to use positron emission tomography in conjunction with glucose clamps and specific positron-labeled isotopes to measure the kinetic steps of glucose delivery, transport, and phosphorylation in skeletal muscle and to image glucose metabolism in adipose tissues.[66,67]

PROTEIN AND AMINO ACID METABOLISM

The 20 amino acids that are the building blocks underlying protein metabolism are an important aspect of intermediary metabolism. However, the details of the metabolic pathway of each amino acid (or class of amino acids) is a diverse topic, beyond the scope of this chapter, and these pathways are well described.[74] Instead, in this section, the interface or interdigitation of amino acids with carbohydrate and fatty acid metabolism will be addressed, notably when amino acid metabolism yields precursors for gluconeogenesis and under the metabolic conditions when amino acids are consumed as substrates for energy production. However, unlike carbohydrate and lipid intermediary metabolism, for which arguably the primary purpose is combustion for energy production, the main purpose of amino acid metabolism is to conserve the overall mass of proteins and support continued turnover or replacement of proteins to ensure intact functional capacity is maintained, and concepts on protein turnover (degradation and synthesis) will be addressed.

Collectively, amino acids circulate in plasma at an approximate concentration ranging between 35 to 65 mg/dL, divisible roughly evenly across the 20 constituents,[43] with some like glutamate and alanine trending toward higher concentrations, as these are integral to nitrogen exchange between tissues. There are active transport mechanisms involved both in the absorption of individual amino acids from the intestinal tract and from plasma into cells. To support protein synthesis the intracellular pool of amino acids must also reflect the entirety of the amino acid alphabet, including both essential and nonessential amino acids. Thus, part of the intermediary metabolism of amino acids, including crucial transamination pathways, is to ensure appropriate proportionality and availability across the amino acid pool, compensating or adjusting for dietary variances, and thereby enabling protein synthesis. The essential amino acids are the ten amino acids for which endogenous synthetic pathways are mostly insufficient to maintain adequate availability, and thus, there is an *essential* reliance on dietary availability. It is in this context of meeting the dietary requirements for essential amino acids, recommendations are for roughly 60 g of protein consumption daily. Though a daily consumption exceeding 100 g is quite common, and it is with these higher levels of consumption that partitioning amino acids toward oxidation and for gluconeogenesis (or even lipogenesis) tends to be a more prominent facet of postabsorptive and postprandial intermediary metabolism.

Upon absorption from the small intestine, amino acids enter the portal venous circulation, a process that tends to lag temporally behind that of glucose. There is a high splanchnic and hepatic fractional extraction of amino acids. These are both sites of relatively high protein turnover, in contrast to the large amount of protein in skeletal muscle, that also turns over but at a significantly slower rate, as does collagen in bone and other tissues. Enterocytes that cover the extensive intestinal epithelial surface themselves have a cell cycle of only several days, and this rapid rate of cellular turnover, together with their rich complement of transporters and enzymes, constitutes a high need for protein replacement; it has been estimated that splanchnic protein turnover is nearly 50% per day. The liver produces circulating plasma proteins (e.g., albumin, clotting factors, transporter proteins), as well as its own abundant enzymatic capacities, and these have a relatively rapid turnover. Albumin, as an example of a hepatic-synthesized protein, has a turnover of approximately 20% per day, while that of immunoglobins is not too dissimilar. In contrast, the turnover of skeletal muscle protein is estimated to be 1% to 2% per day. These are sharp contrasts, essentially dividing the patterns of protein turnover into categories of a fast-turnover (e.g., hepatic, and splanchnic) and a slow-turnover pool.[1]

There is not a dedicated storage form for amino acids, akin to TG for fatty acids or glycogen for glucose, that sequesters amino acids and can then later be mobilized. Instead, proteins are synthesized to fulfill specific essential functions and in accordance with turnover rates for that specific protein. In this sense, the overall mass of protein in the body, approximately 20% of body weight (Table 22.1), is a reserve of amino acids and indeed supplies nearly three quarters of the amino acids utilized in daily patterns of protein breakdown and synthesis, estimated at 300 to 400 g daily, with the remaining one quarter of amino acids utilized daily coming from food ingestion.[10] Excess amino acids beyond immediate needs for protein synthesis must be otherwise metabolized. To enter these pathways, the amino group is deaminated, and ammonia nitrogen is transferred to an α-keto acid, most typically α-ketogluturate. The resulting deaminated product is metabolized to acetyl-CoA, which can then enter oxidative metabolism to yield energy or serve as a substrate for conversion to newly synthesized glucose or to support *de novo* lipogenesis. This exchange of nitrogen carried out by transamination is quite vigorous.[74] In a seminal series of experiments, Schoenheimer and colleagues conducted labeling studies with the stable isotope ^{15}N and observed that, if the label were administered contained in only a single protein or compound, the isotope ^{15}N would nonetheless rapidly and extensively appear in numerous other proteins and amino acids, denoting rapid exchanges within the nitrogen pool of amino acids.[75] There is also an overriding tightly governed balance of nitrogen and an excess of amino acids, created either by higher rates of protein degradation or, more commonly, by ingestion of protein in surplus of that needed for protein balance, lead to higher nitrogen excretion and diversion of the resultant carbon backbone to other pathways. Urea is the pathway for disposal of the ammonia liberated by transamination that accounts for 80% of nitrogen excretion, the high solubility of urea in water making this efficient for nitrogen excretion. Urea synthesis occurs in the liver, and its excretion occurs of course in the kidney. In skeletal muscle, nitrogen liberated by transamination of amino acids can be carried to the liver via the previously cited Cahill cycle, as pyruvate can accept the nitrogen to form alanine, thereby carrying both a triose carbon backbone for gluconeogenesis and shuttling the nitrogen for urea synthesis. Another fate for the α-ketogluturate that is generated from an amino acid undergoing deamination is to be oxidized. An estimate of the contribution of protein to substrate oxidation can be based on the amount of urinary nitrogen. Approximately 1 g of urinary nitrogen arises from the oxidation of approximately 6.25 g of protein oxidation.[5] On a protein intake of approximately 1 g per kg body weight, typical of a modern diet, nitrogen excretion is approximately 10 g per day, representing approximately 60 g of protein oxidation daily. This compares with an average daily combustion by the brain alone of 120 g of glucose but is about on par with a combustion of about 60 to 70 g of fat daily, though the energy yield of fat is more than twice that of protein.

Altogether it is estimated that there is approximately 300 to 400 g of protein turnover daily, thus greatly exceeding the 60 to 100 g of daily protein ingestion.[1,10] Yet, despite this relatively large daily turnover of protein, the protein mass of the body remains highly conserved and is large, comprising 20% of body weight; viewed from another perspective, it comprises approximately three quarters of the solid mass of the body (this of course excludes the 60% of weight attributable to water and that due to anhydrous fat). For instance, skeletal muscle comprises approximately 40% of weight in a lean adult, and approximately 20% of muscle weight is represented by protein, and thus 5 to 6 kg of protein in muscle in a 70-kg adult. At the 1% turnover rate, it can be estimated that approximately 50 to 60 mg of skeletal muscle protein is degraded and synthesized in a balanced homeostasis each day. The role of exercise in influencing contractile protein turnover in muscle will be addressed later. Endocrine regulators of protein synthesis are insulin, growth hormone, and testosterone, which have an anabolic effect, whereas cortisol has a catabolic effect. Also of obvious importance for protein synthesis is a high availability of amino acids, and so in this sense, protein synthesis can be generally regarded within the panoply of postprandial anabolism. Exercise can stimulate protein synthesis in skeletal muscle (and in the heart), especially for several hours in the postexercise period when a previous bout of exercise can augment the effect of food and protein ingestion to stimulate muscle protein synthesis. As well, exercise can shape the remodeling adaptation of a specific muscle to adjust to repeated exposure to an exercise, and these effects are more pronounced in response to resistance types of exercise.

KEY POINTS: Protein and Amino Acid Metabolism

- Key function of amino acid metabolism is to ensure appropriate availability across the amino acid pool to facilitate protein synthesis, compensating or adjusting for dietary variances.
- Essential amino acids are designated as the ten amino acids for which there is an *essential* reliance on dietary availability.
- Protein stores in the body supply most of the 300-400 g of amino acids required for daily protein breakdown and synthesis, the remaining amino acids are supplied from ingested food.
- The liver produces circulating plasma proteins.
- Amino acids not utilized for protein synthesis are deaminated to yield products for oxidative metabolism, gluconeogenesis or de novo lipogenesis.

EXERCISE METABOLISM

Exercise Dramatically Increases Demand For Energy

Exercise and other forms of physical activity can dramatically increase energy expenditure, and these robust demands for energy mobilization and utilization involve unique metabolic regulation that require hormonal control as well as hormone-independent mechanisms (Fig. 22.3). The resting metabolic rate or energy expenditure is approximately 5 mL O_2 consumption per kg body weight per minute. During moderate exercise O_2 consumption can increase 10-fold, and in elite athletes O_2 consumption during maximal exercise can be as high as 90 mL per kg body weight per minute, an astounding 18-fold increase from rest. This increase is almost exclusively due to the increase in energy demand by contracting skeletal muscle, and to a lesser extent the rapidly beating heart.

KEY POINTS: Exercise Metabolism

- Increases in epinephrine during moderate to high intensity exercise stimulates glycogen breakdown to supply glucose to contracting skeletal muscle.
- Low circulating insulin and elevated glucagon during exercise help to increase hepatic glucose output to maintain blood glucose levels during exercise.
- Lactate and amino acid production by exercising muscle can be converted back to glucose in the liver where it is subsequently delivered back to exercising muscle via the circulation.
- The need for exogenous insulin and impairments in counterregulatory responses to hypoglycemia in Type 1 diabetes makes the regulation of blood glucose during exercise problematic for these patients.
- Low circulating insulin and elevated glucagon during exercise act to stimulate lipolysis of triglycerides within adipose tissue to increases fatty acids in the circulation for delivery to exercising muscle.
- Elevated epinephrine during moderate to high intensity exercise stimulates hydrolysis of triglycerides stored within skeletal muscle to supply fatty acids to contracting skeletal muscle.
- Exercise training increases the availability of carbohydrate and lipid fuels and the metabolic machinery to store, mobilize and utilize these fuels to support the energy demands of exercise. Exercise training also shifts fuel preference towards fatty acid oxidation in the postabsorptive (fasting) state and increases insulin sensitivity in the postprandial (fed) state.

Energy Metabolism During Exercise

The control of metabolism to supply energy during exercise involves most of the same systems of hormonal regulation described for postabsorptive metabolism, but often on a different level of magnitude and also involving unique mechanisms, some of which are only beginning to be understood. The increase in energy expenditure during exercise is supported by multiple systems in skeletal muscle. During high intensity exercise lasting up to several seconds, such as sprinting or weightlifting, stored phosphocreatine supplies energy in the form of ATP catalyzed by the creatine kinase (CK) enzymes. An additional function of CK is thought to be a buffer against increasing adenine diphosphate (ADP) concentrations, because ADP is a key regulator of many enzymatic reactions in the cell. CK is highly abundant in skeletal and cardiac muscle, and clinically, elevated CK levels in blood are used to diagnose damaged cardiac muscle (myocardial infarction) and skeletal muscle disease (muscular dystrophy).

Glucose Metabolism During Exercise

During exercise of lower to moderate intensity, energy can be provided by both glucose and fatty acids. Exercise of moderate to relatively high intensity relies predominantly on glycolytic or anaerobic metabolism, predominantly through the breakdown of glycogen stores in muscle.[76] This rapid increase in glycogen breakdown is regulated by mechanisms involving catecholamine stimulation of the adenylate cyclase reaction to ultimately activate glycogen phosphorylase, along with endogenous calcium activation released through muscle contraction.[77] Glycogen stores in skeletal muscle (Fig. 22.4) are limited to approxiamtely 400 g (1600 Kcal) (Table 22.1) and can be a limiting factor in marathon running or other long-duration endurance sports. Fortunately, other fuel sources can supply energy for exercise. The liver is remarkable in its ability to increase HGP to maintain blood glucose levels even during strenuous exercise. Even during moderate intensity exercise there are increases in glucagon and catecholamines, and a concomitant decrease in insulin secretion, that in concert enable increased HGP; HGP can increase many fold.[78] This effect on HGP and the accompanying endocrine response is more subtle during mild intensity exercise, such as walking, even when sustained. During a bout of moderate exercise

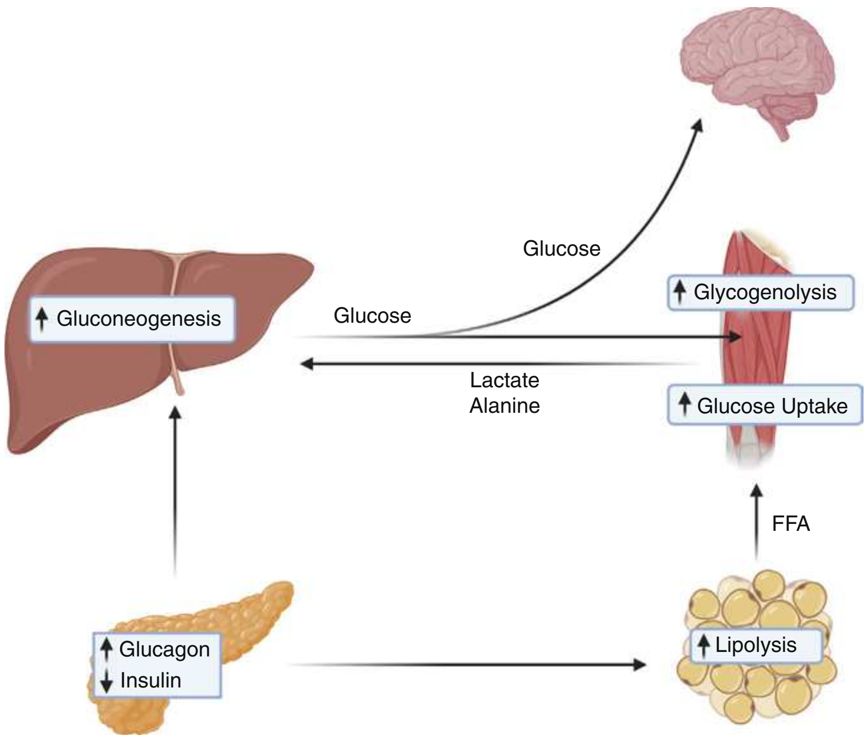

Fig. 22.3 **Exercise metabolism.** Glycogenolysis and insulin-independent glucose uptake are rapidly accelerated during exercise and compensate for the low circulating insulin levels, which also serve to release the suppression of lipolysis within adipose tissue and enable increased HGP. This synergizes with higher epinephrine and norepinephrine, which act to increase triglyceride hydrolysis in adipose tissue and skeletal muscle and increase glycogenolysis in skeletal muscle. The high rates of glucose metabolism result in the release of lactate and alanine, particularly during higher intensity exercise, which are then transported to the liver and converted back to glucose via the Cori and Cahill cycles, all of which markedly increase energy supply to skeletal muscle. A caveat to this description of intermediary metabolism during exercise is that the fuel admixture combusted during physical activity is strong influenced by the intensity of the exercise, the duration of exercise, and the underlying fitness of the individual. In general, lower to midlevel intensity exercise, a longer duration of such exercise, and a higher level of fitness are factors that act to increase reliance upon fatty acid oxidation rather than upon glucose metabolism. *FFA,* Free fatty acid.

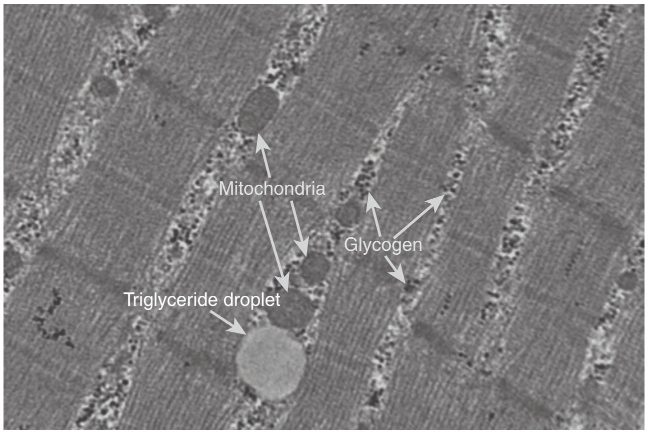

Fig. 22.4 Electron micrograph of human skeletal muscle (vastus lateralis) illustrating fuel stored as glycogen and as triglyceride in lipid droplets, and held in close proximity to mitochondria for efficient oxidative metabolism.

muscle cells take up and utilize glucose from the circulation supplied by the liver. This process is dependent on glucose transport via the GLUT4 glucose transporter, described in the sections on postabsorptive and postprandial metabolism, whereby these GLUT4-containing vesicles are translocated from the cytosol to the sarcoplasmic membrane and T-tubules. The mechanisms governing this GLUT4 translocation and glucose transport differ from that described above for insulin-stimulated glucose transport after feeding. Circulating insulin levels during exercise are quite low, necessitating a separate mechanism involving the signaling molecules AMPK, calcium, and nitric oxide.[79] The fate of this glucose once inside the cell can be complete mitochondrial oxidation or, during higher intensity exercise where oxygen is limiting, the glucose supplies energy through glycolysis but with pyruvate converting to lactate rather than continuing to oxidative pathways. If this high intensity exercise continues, the lactate in muscle is exported into the blood, where it can be produced at a faster rate than it can be cleared by the liver and converted back to glucose via the Cori cycle, thus resulting in an accumulation of lactate in the blood. In this scenario, lactate levels can increase from a resting level of approximately 1 mmol/L to upwards of 15 to 20 mmol/L. It is this acute increase in lactate during exercise with the increase in associated H^+ (acid) that reduces the blood pH significantly and results in muscle fatigue and the need to reduce exercise intensity or to completely stop exercise.

Patients with type 1 diabetes mellitus require insulin for survival, and this need makes the regulation of blood glucose during exercise problematic for these individuals. Because insulin and exercise itself have independent effects on glucose uptake, having an inappropriately higher amount of circulating insulin due to giving too much insulin prior to exercise will effectively add to the independent effects of muscle contraction on glucose uptake and cause excessive decreases in blood glucose, and hypoglycemia may ensue. Also, a relative excess of circulating insulin impedes the increase of HGP. Furthermore, the counterregulatory responses to hypoglycemia are impaired in type 1 diabetes mellitus, i.e., increases in catecholamines and glucagon.[80] Thus, this hormonal dysregulation and absolute lack of insulin in type 1 diabetes mellitus highlights the independent effects of exercise and insulin on glucose uptake and why having the right balance of exogenous insulin before, during, and after exercise is critical in type 1 diabetes mellitus.

Fatty Acid Metabolism During Exercise

The increase in the demand for energy during exercise can also be supported by fatty acids. The source of these fatty acids can vary according to availability, as well as the intensity and duration of exercise. A considerable portion of the fatty acids comes from the circulation, resulting from their release by adipose tissue TG hydrolysis. Low circulating insulin levels during exercise act to release the brake on lipolysis, thereby allowing more fatty acids to be released into the circulation and taken up by exercising muscle. In addition, epinephrine stimulates lipolysis and hydrolysis of adipose tissue TG by activating HSL as well as TG within circulating VLDL. The fatty acids that are free in circulation are taken up and oxidized by skeletal and cardiac muscle through beta oxidation and mitochondrial oxidative phosphorylation. During low-intensity exercise such as walking, plasma fatty acids comprise the major fuel source for exercising muscle and accordingly, given the enormous fuel reserve of TG in adipose, fuel availability is not a constraining factor, as contrasted with the much more finite reserve of muscle glycogen needed to support high intensity exercise.

Fatty acid oxidation during exercise can also be supported by the hydrolysis of TG stored inside muscle cells themselves (Fig. 22.4). This source of energy can supply approximately 50% of the fatty acid oxidation in exercising muscle.[81] Fig. 22.4 illustrates the location of these TG droplets adjacent to mitochondria. These LDs replete with TG are accompanied by LD proteins, perilipins, as well as lipases that are critical for TG hydrolysis and release of fatty acids close to mitochondria.[82] Given the need for fatty acid transport proteins in the aqueous cellular environment, this subcellular geography is important for the process of fatty acid storage, mobilization, and oxidation during exercise.

Effects of Exercise Training on Intermediary Metabolism

Chronic exercise training results in a plethora of changes and adaptations, which largely act to enhance both the availability of carbohydrate and lipid fuels and the metabolic machinery to store, mobilize, and utilize these fuels to support the energy demands of acute exercise bouts. Exercise training increases insulin sensitivity (see earlier section on postprandial metabolism), which serves to enhance rates of glycogen synthesis, and, along with increased enzymes regulating glycogen storage, culminates in an increase in the amount of glycogen storage. Because low muscle glycogen limits long-duration exercise performance, increasing glycogen storage in muscle can enhance exercise performance.[83] This limitation in muscle glycogen storage and in endogenous glucose production by the liver led to decades of research and billions of dollars spent on sports nutrition products to supplement glucose availability during bouts of exercise.

Exercise training also enhances storage of TGs in skeletal muscle, an important fuel source for exercising muscle. Interestingly, excess storage of muscle TGs in conditions of low physical activity and overnutrition, i.e., obesity, is associated with insulin resistance and increased risk for type 2 diabetes.[84] One of the most important adaptations that can occur with exercise training is the increase in the cellular machinery to mobilize, deliver, transport, and utilize both carbohydrate and fat fuels. Prominent among these adaptations are robust increases in mitochondria content and associated enzymes to enhance capacity for oxidative metabolism. These changes induced by training consequently enhance the capacity to perform exercise longer and at a higher intensity. Moreover, exercise training enhances regulation of both postabsorptive and postprandial metabolism, as discussed earlier, e.g., enhanced insulin sensitivity, fatty acid oxidation, and overall metabolic flexibility, and has a multitude of effects that reduce body fat and reduced risk for type 2 diabetes and cardiovascular diseases.

SUMMARY AND CONCLUDING REMARKS

Intermediary metabolism is a complex constellation of processes, principally enzymatic reactions, by which nutrition is converted into components that can be utilized to produce energy, stored in forms that can later be mobilized, and that can serve to support anabolic actions in the building of cellular and organ structure. In this chapter, emphasis was placed upon the roles of various organs, notably, brain, liver, adipose, and skeletal muscle, and how the integration of, and exchanges between, these individual organs comprise systemic intermediary metabolism. In particular, the concept of interorgan substrate flux was delineated as an integrated physiological aspect of metabolism, and it was emphasized how endocrine governance of intermediary metabolism can be largely understood by examining the effects on modulating rates of glucose and fatty acid flux. Another fulcrum of control in intermediary metabolism that was emphasized was the control of glucose and fat oxidation, how this partitioning is most fundamentally controlled by relative substrate availability and can manifest competition between carbohydrate and lipid metabolism, and how this substrate competition is kept salutary by endocrine actions. Hopefully, it has been useful to frame the delineation of intermediary metabolism in a context of three common daily experiences—fasting, feeding, and physical activity—and explore the deceptively, or seemingly silent, sharp changes that mark transitions from feeding to fasting and then back to fasting, and in response to exercise.

OBESITY AND ITS HEALTH CONSEQUENCES

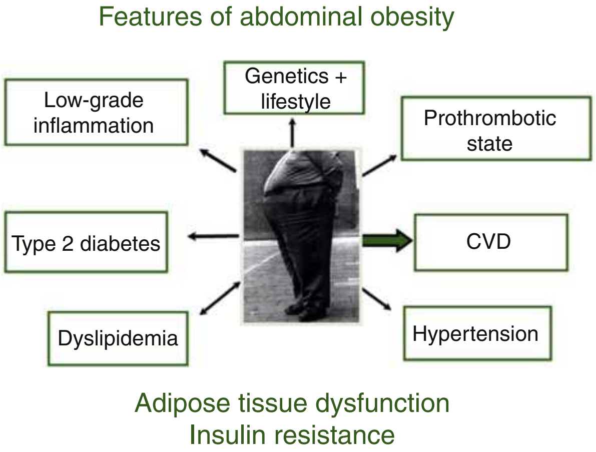
Our changed lifestyles with less physical activity and easy access to calorie-dense fast foods have caused a global epidemic of obesity. This has also led to an increase in obesity-associated chronic diseases, including cardiovascular disease, diabetes, fatty liver disease (nonalcoholic fatty liver disease [NAFLD]/nonalcoholic steatohepatitis [NASH] and nonalcoholic liver cirrhosis), osteoarthritis, and dementia, as well as liver, breast, and colon cancer. Fig. 23.1 shows a typical Caucasian individual with obesity and summarizes some common chronic disorders and characteristics.

Epidemiologically, the degree of obesity is usually expressed as body mass index (BMI), which is measured as body weight in kg/height in meters^2. Table 23.1 shows current BMI definitions of normal weight, overweight, and different degrees of obesity. Based upon current US trends, it is predicted that by 2030 around 50% of adults will be obese, and, of these, 25% will have severe obesity, with a BMI over 35 kg/m^2.[1] In addition to the rising prevalence of obesity, an additional concern is that obesity also manifests earlier in life, resulting in an earlier initiation and greater duration of the associated chronic diseases. The prevalence of obesity is increasing rapidly in several Asian countries, while it seems to have reached its peak in many European countries. Nevertheless, the current global obesity epidemic is a major challenge to population health and entails rising health costs. A large international age-adjusted study of global mortality in relation to relative degree of obesity measured as BMI showed that mortality in adults increased almost linearly with increasing BMI. Compared with a normal BMI of 18.5 to 25 kg/m^2, set to a hazard ratio (HR) of 1.0, overweight increased HR to 1.2, grade 1 obesity to 1.45, grade 2 obesity to 1.94, and grade 3 obesity to 2.76.[2] This documents the global health problem of obesity.

Although death from myocardial infarction has declined in several countries due to reduced smoking, better hypertension/lipid control, and technological advances in cardiac interventions, the prevalence of heart failure increases due to obesity. Other comorbidities associated with obesity have also become global epidemics, in particular diabetes and its different complications. The International Diabetes Federation[3] estimates that in 2019 the global prevalence of diagnosed diabetes was 463 million people, while an additional 232 million had undiagnosed diabetes. The global health expenditures due to diabetes are estimated to constitute around 10% of the total healthcare costs.[3] Thus, obesity is a major global health problem, and the healthcare system has to a large degree failed to establish treatments resulting in sustained body weight loss. While bariatric surgery is efficient in some of the most severe cases, it will never constitute a global treatment option. The pharmaceutical industry is therefore keen to developing new agents targeting appetite regulation and energy expenditure. In the United States, unlike in most other Western countries, life expectancy has been decreasing in recent years. Although many factors may contribute, the high incidence of obesity in this country is likely to be a causal factor.

Different Types of Obesity and Associated Health Risks

Although BMI is used as an indicator of relative obesity, it has long been recognized that the condition is not homogeneous, and that different types of obesity, related to body fat distribution, are also associated with a lower or higher risk of developing cardiovascular disease,



Features of abdominal obesity
Genetics + lifestyle
Low-grade inflammation
Prothrombotic state
Type 2 diabetes
CVD
Dyslipidemia
Hypertension
Adipose tissue dysfunction
Insulin resistance

Fig. 23.1 Features of Abdominal Obesity. *CVD,* Cardiovascular disease.

TABLE 23.1 Definitions of Obesity and Waist Circumference Thresholds

Relative Degree of Obesity, Bod Mass Index, kg/m^2	Waist Circumference Thresholds, cm	Waist Circumference Thresholds, cm
	Males	*Females*
Normal weight 18.5–24.9	>90	>80
Overweight 25–29.9	>100	>90
Obesity, Grade 1 30–34.9	>105	>110
Obesity, Grade 2 35–39.9	>125	>115
Obesity, Grade 3 40–60	>125	>115

Fig. 23.2 Adipose Tissue Expansion Through Hypertrophy or Hyperplasia and Consequences for Ectopic Fat Accumulation.

diabetes, and other complications. In fact, adipose tissue is a good example of something of which both too much and too little can be harmful, as individuals with lipodystrophy, i.e., lacking areas of adipose tissue, show the same health risks and similar metabolic aberrations as individuals with obesity and expanded adipose tissue.

The subcutaneous adipose tissue (SAT) is the largest adipose depot of the body and also the most efficient and least harmful site to deposit excess lipids. The SAT expands by recruiting new adipose cells (hyperplasia) and/or by expanding the size of available cells (hypertrophy). Adipose cells are unique in their ability to expand and store lipids, as they can inflate in size by at least 10-fold! There is a continuous turnover of adipocytes in SAT of around 10%/year. Recruitment of new cells is essentially limited to before puberty,[4] although it seems that thigh/gluteal SAT can continue to recruit new cells in adult females.[5] Expansion of SAT by hyperplasia is less harmful, while hypertrophic growth is metabolically harmful and leads to a dysfunctional and inflamed adipose tissue, development of dyslipidemia, systemic inflammation, and local and systemic insulin resistance which, in turn, promote the risk of developing obesity-associated complications.[6] There are also other adipose tissue depots, including the visceral (intraabdominal) site, which has long been considered a marker of metabolically unhealthy obesity due to its close association with diabetes, cardiovascular disease, and NAFLD/NASH.[7] Over 50 years ago, this prompted the subdivision into “apple” versus “pear”-shaped obesity, where the former (also termed “abdominal type,” see Fig. 23.1) is more closely associated with health complications. The reason for each individual’s propensity to develop apple/abdominal or pear/peripheral obesity is unclear, but genetic factors play a role, in addition to gender, as women are more likely to have peripheral, and therefore less harmful, obesity, at least before the menopause. After menopause, women can also develop an abdominal type of obesity.[7]

The most simple and commonly used measure of abdominal versus peripheral obesity is waist circumference. There is ample evidence establishing the increased health risk of a large waist circumference for any given BMI. This has led to a recent Consensus Statement by the International Atherosclerosis Society that risk assessments of developing cardiovascular disease and other obesity-associated complications should include BMI *and* waist circumference.[8] Other institutions and governmental bodies, such as the World Health Organization and National Institutes of Health, have also issued recommendations on how waist circumference should be measured and stated that waist circumferences over 88 cm in women and 102 cm in men indicate an increased risk of complications, independent of BMI. However, it is also clear that increased obesity itself leads to expansion of the waist circumference, suggesting that the waist circumference should also be stratified according to BMI, and this is included in the Consensus Statement.[8] Importantly, there are also ethnic differences, and the recommended waist circumference thresholds in Japanese and Asian populations are generally lower than those in Caucasians.

Increased waist circumference is a marker of expanded visceral/intraabdominal adipose tissue, which reflects the available SAT cells becoming saturated with stored excess lipids, which, in turn, leads to increased ectopic lipid storage in other organs/tissues that can store lipids.[9] This is supported by the close association between the amounts of visceral fat and liver lipids (NAFLD/NASH) and also with the accumulation of ectopic lipids in skeletal muscles, pancreas, and heart (Fig. 23.2), with negative metabolic consequences and health risks. The ability of the subcutaneous adipocytes to expand makes their size an excellent marker of adipose tissue health and function, and also of systemic consequences, including degree of insulin resistance. This has been shown in many studies and is exemplified by the finding that the degree of reduction of subcutaneous cell size following bariatric surgery is a considerably better marker of improved insulin resistance than the amount of weight lost.[10] Extensive *in vivo* characterization has shown that subcutaneous adipose cell size is a marker of both the amount of ectopic fat accumulation and the degree of systemic insulin resistance.[11]

It should also be stressed that BMI is not a sufficiently sensitive measure of dysmetabolic state and health risk, given that around 20% to 30% of individuals with normal BMI exhibit insulin resistance and increased risk of developing diabetes and cardiovascular disease. Conversely, a similar proportion of people with obesity can be metabolically healthy; although epidemiological studies have shown that they still have an increased risk of developing diabetes and cardiovascular disease, this risk is considerably less than in weight-matched individuals who display a dysmetabolic state.[12] These data again show that BMI is not sufficiently sensitive at an individual level and indicates situations where additional markers such as waist circumference, or preferably subcutaneous adipose cell size (although not easy to measure in routine clinical settings), are helpful. It would be valuable to have early, sensitive, and clinically useful markers of an individual's that could predict the health risk associated with future weight increase and identify SAT dysfunction at an early stage. The only currently identified genetic marker of adipose cell size and health risk is related to the *KLF14* gene, primarily in females,[13] although another study[14] suggested that it was related to the risk of developing cardiovascular disease in both genders. Several other genes have also been shown to be associated with adipose cell differentiation and storage capacity, but with little individual impact.[15]

KEY POINTS

- Subcutaneous adipose tissue can expand through hyperplasia and, most commonly in adults, through hypertrophy. Expanded subcutaneous adipose cell size and increased waist circumference are indicators of the future risk of developing diabetes and cardiovascular disease.

Another condition of inherently dysfunctional adipose tissue has been identified in individuals with a genetic propensity for type 2 diabetes. Around 30% of first-degree relatives (FDRs) of individuals with type 2 diabetes exhibit an inappropriate increase in subcutaneous adipocyte size for any given BMI, indicating that they can be metabolically obese even at a normal BMI. It is also well-established that FDRs have a very high risk of developing both type 2 diabetes and cardiovascular disease.[16] This sensitivity to the environment is proposed to depend on an inherent (possibly genetic) reduction in the number of available SAT progenitor cells able to undergo differentiation, thus promoting inappropriate hypertrophic expansion of the adipocytes, resulting in dyslipidemia and insulin resistance. This is best seen in the nonobese state,[17,18] because adipose cells also have a finite expansion capability in obesity, and is also seen in nonobese individuals with type 2 diabetes.[19] However, much work needs to be done to better understand the interactions between the environment and adipose tissue genetics.

Summary

The current global epidemic of obesity is a major threat to both individual health and health expenditures. Obesity promotes metabolic dysfunctions including insulin resistance and dyslipidemia and is a major risk factor for developing cardiovascular disease, diabetes, liver disease, cognitive dysfunction and several forms of cancer. While the degree of obesity is commonly stratified by BMI, an individual risk score should also include waist circumference. The SAT has a limited ability to expand and, when exceeded, it leads to accumulation of ectopic fat in many organs/tissues enhancing health risks.

ADIPOGENESIS AND ITS REGULATION

Adipose Cell Differentiation and Role of Genetic Factors

White adipose tissue is a complex tissue consisting of several different cell types that exhibit close crosstalk with and balance among each other to ensure a healthy and functional tissue. The tissue contains uncommitted mesenchymal stem cells, committed preadipocytes at different stages of differentiation, immune cells of different types, and endothelial cells that regulate lipid transport to/from the blood and fibroblasts. As described above, adipose tissue expansion is dependent on the increase in size of differentiated and mature adipocytes (hypertrophy) and/or the induction of commitment and further differentiation of new adipocytes (hyperplasia) from existing progenitor cells, as well as further differentiation of the preadipocytes. In humans, the uncommitted progenitor cells are both of mesenchymal stem cell origin, as well as of hematopoietic (bone marrow) origin. Surprisingly, studies have shown that, in humans, around 10% of the progenitor cells are derived from the bone marrow.[20]

The undifferentiated mesenchymal stem cells are multipotent and can be differentiated *in vitro* to adipocytes, osteocytes, and chondrocytes, depending on environment and specific spatiotemporal differentiation signals. Commitment of both human and murine stem cells into the white adipogenic lineage is dependent on bone morphogenetic protein (BMP) 4,[21] while brown adipose cell (see later) commitment seems to be more dependent on BMP 7.[22] Following initial commitment into the adipose cell lineage, a complicated sequence of events involving a number of different temporally induced transcription factors promotes full differentiation. Among these, C/EBPα and PPARγ are essential to inducing and maintaining a differentiated adipocyte phenotype.

Many studies have shown that adipose tissue is a major regulator of whole-body insulin sensitivity, inflammation, and metabolism through its secretion of different adipokines and cytokines, as well as lipid storage and regulation of lipolysis. Dysfunctional adipose tissue is characterized by insulin resistance, elevated lipid levels, and increased systemic inflammation. Hypertrophic, rather than hyperplastic, expansion leads to dysfunctional adipose tissue and a dysmetabolic state, with increased risk of developing cardiovascular disease, diabetes, and other complications. It is clear from both *in vivo*[23] and *in vitro* studies[24] in humans that hypertrophic expansion of subcutaneous adipose cells is a consequence of a reduced ability to recruit and differentiate new adipose cells, and that there is also a negative correlation between estimated adipose cell number and cell size in humans.[25]

Several studies have identified a large number of genes related to an individual's ability to safely enhance SAT lipid storage and shown that these genes are also associated with a reduced risk of developing diabetes.[26] Genes related to adipose tissue distribution are also markers of adipose tissue cell size and metabolism.[25] As discussed earlier, individuals with a genetic predisposition for type 2 diabetes (FDRs) are also characterized by markers of reduced subcutaneous adipogenesis and inappropriately expanded cells for a given BMI. This is most clearly seen in nonobese individuals, because there is finite expandability of adipose cells in obesity. Together, these data support the concept that genetic factors regulate SAT expansion and distribution, and that these factors are associated with the metabolic state and insulin sensitivity.

There is much additional experimental support for this concept; for instance, it has been shown that functional mutations of PPARγ, the key transcriptional regulator of adipogenesis, are associated with an approximately 8-fold increase in the risk of developing diabetes.[27] Although these mutations are rare, they support the importance of a properly functioning SAT in reducing the risk of developing type 2 diabetes. As discussed later (in the Therapy section), this is also supported by the clinical use of the PPARγ ligands, the thiazolidinediones (TZDs), to treat type 2 diabetes. TZDs enhance differentiation of existing preadipocytes, thereby improving lipid storage capacity in the SAT and the release of beneficial adipokines such as adiponectin, while tissue inflammation is reduced. This leads to improved insulin sensitivity, lower plasma glucose levels, and reduced ectopic lipids in the liver and elsewhere while the SAT expands.[28]

KEY POINTS

- Adipose tissue is a major regulator of whole-body insulin sensitivity, and expanded adipose cell size is a marker of dysfunctional tissue. PPARγ ligands (thiazolidinediones) can increase recruitment of new adipose cells, and this is associated with enhanced insulin sensitivity.

Role of Aging and Cell Senescence

The most important general risk factor for many chronic diseases, including cardiovascular disease and diabetes, is aging. Aging (age >75 years) is associated with a reduced number of functional cells in many tissues, including heart, skeletal muscle, and adipose tissue, and an increased in fibrosis and tissue inflammation. The reason for this is that normally proliferating progenitor cells undergo proliferative senescence with aging that inhibits their ability to proliferate, differentiate, and replace dying cells. Senescent cells have left the cell cycle and become proinflammatory, and also secrete a number of different cytokines and chemokines, proteases, DNA, microRNA, and fibrotic factors: the so-called senescence-associated secretory phenotype (SASP).[29] Secretion of SASP-associated factors to neighboring cells, and systemically, also means that normal, nonsenescent cells become targets and inhibited from undergoing normal differentiation.

Many animal studies have shown that, with aging (defined as mice older than 12 months), the adipose tissue becomes smaller and displays fewer cells.[30]. In humans, it is more difficult to define a specific age for adipose-associated senescence, given that lifestyles are very variable; for instance, levels of physical activity, which prevents induction of cell senescence,[31] may remain high even in individuals of advanced age. However, pooling large databases showed a gradual increase in the relative amount of visceral fat with age, which probably also reflects changes in the amount and cell size of the SAT, even though this was not measured.[7] Insulin sensitivity is also reduced with aging in humans, but, again, defining specific ages is difficult, given that lifestyle has such an important impact on insulin sensitivity. Nevertheless, aging becomes gradually associated with reduced numbers of functional cells in most tissues and combined with enhanced inflammation in both animals and humans. However, aging is only one of several factors that promote cell senescence; other factors include DNA damage, inflammation, increased reactive oxygen species, and others.[32]

As discussed above, the number of subcutaneous adipose cells measured in the abdominal site apparently becomes fixed around the time of puberty.[4] This means that, when these cells have become fully differentiated to adipose cells and accumulated lipids, additional expansion is primarily achieved by hypertrophy, with the metabolic consequences discussed. However, there is also regular turnover of the adipose cells, with a half-time of around 10 years. With aging and increasing cell senescence there will be fewer functional progenitor cells to replace the dying adipose cells, thus leading to further expansion of the available cells. Hypertrophic expansion of the adipose cells is thus a marker of reduced availability of new progenitor cells to differentiate, as has been observed clinically.[33] Similarly, extensive studies with human adipose progenitor cells *in vitro* have shown that individuals with hypertrophic expansion of the adipose cells are also characterized by impaired differentiation of new cells.[24] Because the number of progenitor cells is apparently not reduced, these data suggest that hypertrophic expansion of the adipose cells in adult humans could be associated with increased cell senescence preventing normal differentiation of progenitor cells. In fact, this is exactly what was found with progenitor cells from individuals with hypertrophic obesity, and this was even further pronounced in cells from type 2 diabetic individuals.[34] Importantly, increased cell senescence was also seen in nondiabetic individuals with a genetic predisposition for type 2 diabetes (FDRs), who also exhibited markers of inappropriate expansion of the subcutaneous adipose cells, as discussed.

KEY POINTS

- Increased adipose cell senescence is associated with aging and chronic diseases and means that the adipose progenitor cells can not undergo proliferation as needed to replace dying cells. Senescent cells become proinflammatory and secrete inflammatory and other factors (senescence-associated secretory phenotype) that target and alter ambient cells.

Although senescent progenitor cells cannot undergo differentiation, the number of such cells in human adipose tissue is usually not more than around 10%, even in type 2 diabetic individuals. However, the consequences of cell senescence are amplified by their secretion of SASP-associated factors, which target neighboring, as well as peripheral cells, inhibiting their normal differentiation via para-and endocrine effects. Thus, conditioned tissue culture medium from senescent cells added to nonsenescent cells inhibits normal differentiation of the latter. Interestingly, it is not only the adipose progenitor cells that become senescent, but also the endothelial cells in adipose tissue, which has negative consequences for lipid transport in and out of the tissue[35,36] and contributes to systemic dyslipidemia. To what extent other cells in the adipose tissue also become senescent and what consequences this has needs to be studied.

Summary

Adipose tissue is a major regulator of whole-body insulin sensitivity, but when adipose cells expand (hypertrophic obesity), insulin sensitivity is reduced and inflammation and lipid levels increase, together with the risk of developing cardiovascular disease, type 2 diabetes, liver disease, and other conditions. This risk can be reduced by taking measures to reduce body weight and/or increase adipose cell storage capacity, including treatment with TZDs. Recent studies have identified cell senescence as a major inhibitor of normal cell differentiation and have found that aging, hypertrophic obesity, and type 2 diabetes involve increased cell senescence in the adipose tissue. Use of senolytic agents in animal models has shown that deletion of senescent cells markedly improves several chronic conditions, raising the expectations for future human treatments when potential safety issues have been clarified.

IMMUNOMETABOLISM: ITS REGULATION AND ROLE IN INSULIN RESISTANCE, INFLAMMATION, AND DISEASE

Inflammation is a physiological consequence that follows exposure to external and internal stressors and involves an acute response characterized by redness (rubor), heat (calor), pain (dolor), swelling (tumor), and dysregulated cellular/organ function (functio laesa).

That inflammation could be linked to metabolic diseases such as obesity and type 2 diabetes was known already in the nineteenth century, when salicylate was proposed as a treatment against obesity-associated diabetes. However, whether this effect was linked to adipose tissue was unknown. While the notion of inflammation as a culprit driver was subsequently established in a number of other diseases, its role in white adipose tissue was for a long time disregarded. It was not until the early 1990s that it was demonstrated in murine models that obesity and insulin resistance are linked to increased expression and local release of tumor necrosis factor alpha (TNFα) in white adipose tissue.[37] This sparked an intense line of research trying to understand the pathophysiological mechanisms and the role of this response. What soon became clear from these early studies in animals, and later also in human adipose tissue, was that obesity/insulin resistance is associated with a chronic low-grade inflammation that lacks most of the classical symptoms of acute inflammation. Instead, there is increased expression and release of cyto- and chemokines expressed and released from several different cell types, and some of these can act as chemoattractants to promote further infiltration of different immune cells. A plethora of studies have confirmed that adipocytes can indeed express and release several proinflammatory factors, including CCL2 (also termed monocyte chemoattractant protein-1) and interleukin-6 (IL6), while TNFα and IL1β are secreted locally, predominantly from adipose tissue–resident macrophages. The latter are central cell types in the innate immune system and are among the most abundant leukocytes in obese/insulin resistant adipose tissue. Typically, macrophages in the adipose tissue from subjects with obesity/insulin resistance are centered around what are considered to be "dying" adipocytes in crown-like structures. Traditionally, these macrophages display a phenotype more similar to a proinflammatory M1 subtype than to the tissue repair–associated M2 cells. Admittedly, the subdivision into M1/M2 is an oversimplification, and inflamed adipose tissue can display a large panorama of different macrophage subtypes,[38] the roles of which remain somewhat unclear. Moreover, while macrophages are the most abundant white blood cells in inflamed adipose tissue, most types of immune cells can be found therein, including T-cells, B-cells, and different forms of granulocytes.

The inflammatory phenotype described above is linked to a number of morphological changes in adipose tissue, including increased adipocyte size (see also earlier), collagen deposition, fibrosis, and possibly reduced vascularization and hypoxia,[39] although the latter is still debated regarding human white adipose tissue.[40] The functional changes in adipocytes linked to inflammation include increased basal but attenuated hormone-stimulated lipolysis (see also section on lipid turnover), reduced insulin-induced glucose uptake and lipogenesis, and lower adipogenesis. These are all processes where insulin plays a major regulatory role in promoting lipid accumulation, and thereby energy storage. Collectively, this reduction in adipocyte insulin sensitivity[41] will result in reduced lipid storage capacity, and it is therefore possible that the inflammatory response induced under caloric oversupply is an evolutionarily conserved response that helps limit adipose tissue expansion. This response becomes maladaptive under a constant hypercaloric state. It should also be mentioned that data in animal models suggest that a (possibly transient) proinflammatory response may be required for adipose tissue expansion, and that inhibiting this process may result in a pernicious metabolic profile.[42]

KEY POINTS

- White adipose tissue displays a proinflammatory response in the obese/insulin-resistant state that is characterized by an increase in the expression and secretion of chemoattractants in the adipocytes themselves, as well as an increased abundance of resident leukocytes.

KEY POINTS

- The proinflammatory response in white adipose tissue is linked to morphological and functional changes in tissue phenotype. While this chronic activation is detrimental, a transient inflammatory response may be important to allow white adipose tissue expansion.

Linking Inflammation to Insulin Resistance

A number of studies have identified the different mechanisms through which inflammation attenuates insulin signaling. These involve both transcriptional (mediated, e.g., by NF-kB activation) and posttranscriptional effects on different phosphorylation steps in the insulin signaling cascade.[43] Combined approaches, using both cyto-/chemokine blocking antibodies *in vivo* as well as genetically modified animal models (primarily tissue-specific knockouts and transgenic mice), have established the causal role that adipose tissue inflammation plays on insulin resistance. This has spurred substantial interest in targeting adipose inflammation in humans. Several clinical studies have been performed with blocking antibodies targeting cytokines. The first approach to be tested was to inhibit TNFα with a single intravenous injection, which proved unsuccessful in improving metabolic control.[44] Subsequent studies using more established TNFα inhibitors (e.g., infliximab, used routinely in the treatment of rheumatic and inflammatory bowel disease) have not demonstrated significant metabolic effects in subjects with type 2 diabetes. The reasons for this could be multiple and include the possibility that the antibody concentrations were insufficient, the fact that adipose tissue does not release TNFα into the circulation, and/or that antibodies penetrate poorly into the adipose tissue. Moreover, TNFα inhibition in other conditions can cause severe side effects such as serious/fatal infections (e.g., reactivation of tuberculosis). Instead, based on its central role in attenuating cell function in organs such as adipose tissue and the pancreas, several clinical studies have focused on inhibiting IL1β. The IL1 receptor antagonist anakinra and the IL1β-inhibitory antibody canakinumab, originally developed for use in rheumatic diseases, have been studied in randomized, placebo-controlled trials with glycemia and type 2 diabetes incidence as primary outcomes. Anakinra was shown to reduce systemic inflammation (measured as circulating C-reactive protein and IL6 levels) and improve glycated hemoglobin and insulin secretion, although the effects were less impressive than currently available antidiabetic drugs.[45] Canakinumab reduced the incidence of cardiovascular events[46] but had no effect in reducing the incidence of type 2 diabetes in patients with prediabetes at baseline.[47] Moreover, the rate of fatal infections was significantly higher in the canakinumab arm of the study. Altogether, while the effects on adipose tissue were not assessed in either of these studies, the results suggest that targeting inflammation is not a very efficient treatment for obesity—associated insulin resistance and/or type 2 diabetes and the rate of serious adverse events are not negligeble.[48] This indicates that inflammation in adipose tissue may be a consequence rather than a causal factor, and that efficient treatments targeting adipose tissue should focus on the mechanisms that drive inflammation in the first place. In line with this notion, data in genetically modified animals suggest that insulin resistance in adipocytes promotes the development of inflammation, not the other way around.[49]

KEY POINTS

- Therapies targeting white adipose tissue inflammation are not particularly efficient in improving insulin sensitivity/glucose control, suggesting that inflammation is a consequence rather than a causal factor underlying the development of insulin resistance/type 2 diabetes.

Causal Drivers of Insulin Resistance and Inflammation in Human Adipose Tissue?

These aspects have prompted the quest for identification of the drivers of insulin resistance and inflammation in adipose tissue. Much focus has been put on adipocyte size, as cell hypertrophy is closely linked to a proinflammatory adipose phenotype with increased secretion of, e.g., TNFα and CCL2 and reduced insulin sensitivity.[19] It is still unclear how adipocyte size could impact inflammation, but it has been proposed that hypertrophy is a result of reduced adipogenesis, fibrosis, and possibly local hypoxia.[50] Others have suggested that changes in adipocyte metabolism result in an epigenetically-driven change in gene transcription promoting a proinflammatory state. For example, obesity and adipocyte hypertrophy are characterized by lower glutamine levels in the tissue, which promotes an increase in O-GlcNAcylation, a posttranslational modification of proteins and chromatin that activates the transcription and secretion of IL6 and IL1β.[51] This, as well as other changes in adipocyte metabolism, could be part of an evolutionarily conserved response to increases in adipocyte size in order to prepare the tissue for tissue expansion, as discussed previously.

KEY POINTS

- The drivers of WAT inflammation remain unclear but increased fat cell size and disturbances in adipocyte metabolism are believed to be important.

Summary

While adipose tissue inflammation is closely linked to insulin resistance and a pernicious metabolic profile, the causal mechanisms remain unclear and its role as a therapeutic target are probably negligible. Instead, future efforts should aim at identifying the culprit pathways that enable this response which could possibly pave the wave for other treatment approaches.

LIPID METABOLISM IN WHITE ADIPOSE TISSUE

Adipose tissue was long thought to be an inert organ harboring lipids for energy storage and isolation purposes. In the middle of the twentieth century it became apparent that the fat cells within white adipose were very active, displaying marked metabolism of lipids, i.e., storage and release of fatty acids, to control energy homeostasis. These processes are relatively complex with regard to both regulation and physiological/pathophysiological impact, and have been reviewed in detail elsewhere.[52,53] Herein, the most important aspects are discussed, i.e., lipid turnover, lipid synthesis, lipid mobilization, and the impact of glucose metabolism.

Lipid Turnover

Fatty acids are the most energy-rich molecules in the body and are mainly stored as triglycerides in fat cells and liberated through hydrolysis of the triglycerides. Although the fatty acid turnover is mainly driven by storage/release in adipose tissue, other sources are also of importance. These include ingestion during meals, usage for very low density lipoprotein–triglyceride production by the liver, trapping (see later), and oxidation during physical or mental performance. Lipids are stored in mature white fat cells in a single lipid droplet mainly composed of triglycerides. This is different from all other cell types, which display multiple lipid droplets.[54] There is constant turnover of these lipids (Fig. 23.3), which constitutes a single metabolic pool within the lipid droplet in human fat cells.[55] During the 10-year lifespan of a fat cell, triglycerides are turned over approximately six times, irrespective of the size of the lipid droplet. Two adipocyte factors determine the turnover rate, namely the abilities to synthesize (K_{in}) and hydrolyze (K_{out}) triglycerides. The turnover is constant when $K_{in} = K_{out}$. In addition to these kinetic parameters, the turnover is governed by external factors, namely alimentation (mainly influencing K_{in}) and peripheral utilization (mainly influencing K_{out}). Changes in fat cell lipid turnover have clinical implications. Overweight and obesity are characterized by decreased turnover due to increased K_{in} and decreased K_{out}. Dyslipidemia, in particular a genetic form termed familial combined hyperlipidemia, is associated with decreased turnover that is linked to a combination of low K_{in} and K_{out}. It is speculated that this dual kinetic effect "uncouples" fat cells from fatty acid uptake/release and thereby increases the exposure of the liver to fatty acids, which are major substrates for the triglyceride component in lipoprotein synthesis. Differences in lipid turnover can also be observed between adipose depots. As discussed earlier, adipose tissue is distributed into different regions, which display very different sizes. The subcutaneous area is by far the largest (approximately 80% of all adipose tissue). It is believed that this region is a metabolic buffer with high capacity to retain lipids that otherwise would spill over to other tissues such as liver, skeletal muscle, and pancreatic β cells and thereby cause metabolic aberrations.[53,56] The "buffering"

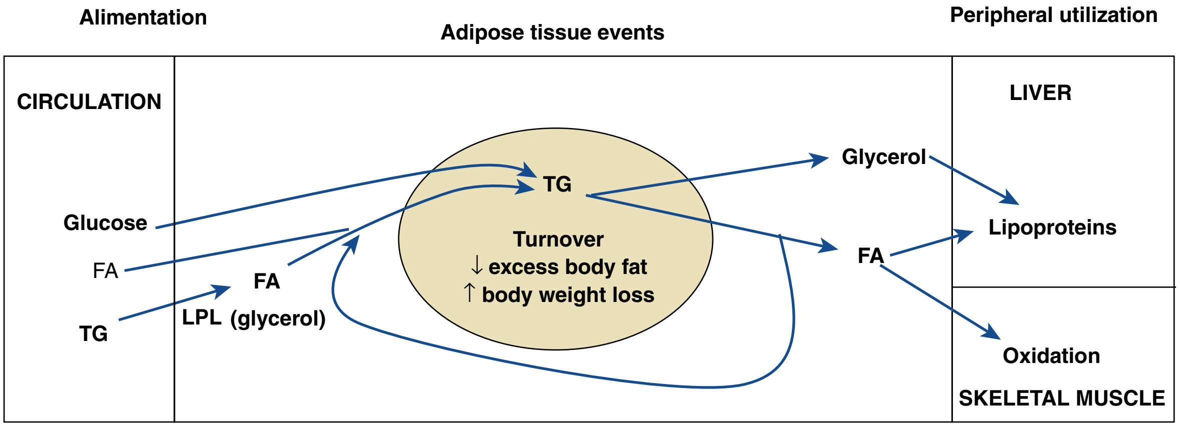

Fig. 23.3 Adipose Tissue Events. *FA,* Fatty acids; *TG,* triglycerides; *LDL,* low density lipoprotein.

capacity is most pronounced in the "lower body" (below the waist line) SAT,[57] which may explain, at least in part, why "upper body" (above the waist line) obesity is more pernicious from a cardiometabolic point of view.[58,59] The size and distribution of SAT is subject to sex dimorphism and differences in lipid kinetics between men and women.[60] In general the depot is larger in women than in men. In addition, women tend to expand lower SAT more than men, while men are prone to accumulate fat in the upper body region. There are no clear-cut differences between the sexes in subcutaneous adipose lipid turnover, although men appear to have less capacity to store and release fatty acids than women *in vivo*. From a pathophysiological point of view the smaller visceral adipose depot has a unique role.[58,61] It is drained by the portal vein to the liver, so fatty acids can directly be delivered to this organ from visceral fat cells and thereby influence lipoprotein and glucose metabolism. The lipid mobilization activity is greater in visceral adipose tissue than in the subcutaneous fat region. This is evident in upper body obesity, and in particular among men, who often have marked visceral adipose accumulation. The consequence is that large amounts of fatty acids are delivered to the liver, causing glucose intolerance and dyslipidemia according to mechanisms detailed elsewhere.[52,53,61] Enhanced peripheral delivery from upper SAT of fatty acids to the liver is also involved in the described pathophysiology. The regional differences in lipid turnover occur *in vivo*.[62] During the gradual transition from leanness to obesity, lipid turnover is lowered in SAT already in the overweight state. Visceral adipose tissue does not change in this way until marked obesity is present. This regional variation may be a factor responsible for higher lipid mobilization from visceral than SAT in less extreme conditions of excess body fat. Finally, lipid turnover is directly involved in changes of subcutaneous fat mass over time.[63] Aging is associated with decreased turnover, mainly due to a decrease in K_{out}, at least in part caused by an age-dependent decrease in catecholamine-stimulated lipolysis. If this is not compensated by a decrease in K_{in}, the subcutaneous fat mass will be expand. Conversely, an increase in K_{out}, such as occurs following bariatric surgery, is associated with long-term maintenance of reduced body weight.

Finally, a recently recognized and potentially important aspect of adipose lipid turnover is so-called fatty acid trapping.[64] These lipid species are not only stored in adipose tissue as triglycerides, they can also be retained within the extracellular space of adipose tissue bound to carriers such as albumin or specific transporter proteins. During esterification and lipolysis (see later) some fatty acids are trapped and not immediately taken up by fat cells or released into the circulation. This is most evident in obesity and dyslipidemia, where fatty acids are trapped in increased amounts and may cause postprandial dysmetabolism according to mechanisms discussed in detail elsewhere,[64,65]

KEY POINTS

- There is a rapid turnover of the triglycerides in the lipid droplet of human fat cells. During the 10-year lifespan of a fat cell, its lipid droplet triglycerides are renewed around six times. Changes in the rate of turnover are important for the regulation of adipose tissue. Decreased turnover is associated with enlargement of the fat mass and with dysmetabolic features.

Methodology

Human fat cell lipid (and glucose) metabolism has been intensely investigated thanks to advanced *in vivo* and *in vitro* methods summarized in Table 23.2. By determining the ^{14}C content in lipids it is possible to calculate their age and estimate the turnover. Fatty acid, glycerol, or glucose tracers can be infused intravenously and used in combination with catheterization or position emission tomography to determine uptake and release of relevant metabolites. Small water-soluble molecules (mainly glycerol, glucose, and lactate) can be measured *in situ* in the water space of SAT by means of microdialysis. Adipose tissue can be excised for ex *in vivo* analyses. Often freshly isolated fat cells are prepared for short-term (hours or a few days) metabolic studies. Finally, precursor cells such as uncommitted mesenchymal stem cells or committed so-called preadipocytes can be isolated from the stroma vascular compartment and cultured for a long time. These precursor cells have been instrumental for understanding the molecular regulation of fat cells, because they can be subjected to genetic transfer and editing.

Lipid Uptake and Lipogenesis in Fat Cells

Fat cells can synthesize triglycerides in several ways; the stepwise esterification starting with glucose and fatty acids is quantitatively the most important one (Fig. 23.3). Fatty acids and triglycerides in chylomicrons or very low density lipoprotein enter the extracellular adipose compartment from the bloodstream. The triglycerides are hydrolyzed by lipoprotein lipase.[66] This enzyme is synthesized by fat cells and excreted to the extracellular space of adipose tissue, where it catalyzes the breakdown of blood-derived triglycerides into fatty acids and glycerol. Glucose is transported into fat cells and metabolized to alpha glycerol phosphate, which is the initial glycerol backbone of triglycerides. The extracellular fatty acids derived from the lipoprotein lipase action, as well as the free fatty acids bound to albumin in the circulation, are transported into fat cells. They are esterified onto the glycerol backbone to form triglycerides. Fatty acids produced by lipolysis (see later) can also be used for triglyceride synthesis in the pathway mentioned earlier instead of leaving the fat cells. This is called reesterification and is quantitatively important; up to 30% of fatty acids produced by lipolysis may

TABLE 23.2 Methods for Studying White Adipose Tissue Metabolism in Humans

Method	Body Level	Main Use
Intravenous infusion of tracers, mainly labeled fatty acids and dexoyglucose in combination with positron emission tomography or catheterization	*In vivo* Whole body or regions	Lipolysis or uptake of glucose and fatty acids by adipose tissue
Catheterization of subcutaneous adipose tissue veins	*In vivo* Abdominal or gluteal regions	Uptake, release, or retention of fatty acids
Microdialysis of subcutaneous adipose tissue	*In situ* Abdominal or gluteal regions	Lipolysis (glycerol levels)
Determination of lipid age by ^{14}C dating	*Ex vivo* (in removed tissue samples)	Lipid turnover studies
Isolated mature fat cells	*In vitro* in living fat cells	Molecular and metabolic studies
Differentiated fat cells	*In vitro* using cell cultures of precursor cells	Molecular, genetic, and metabolic studies

TABLE 23.3 **Species Differences in White Fat Cell Lipid Metabolism**

Event	Humans	Rodents
Hormonal stimulation of lipolysis in adults	Only catecholamines and natriuretic peptides	Numerous hormones, but not natriuretic peptides
Catecholamine signaling	Mainly lipolytic beta 1 and 2 adrenoceptors and antilipolytic alpha-2 adrenoceptors	Lipolytic beta 1, 2, and 3 adrenoceptors; none of the antilipolytic alpha-2 type
Insulin signaling	Through insulin receptor substrate 1 and 2	Through insulin receptor substrate 1, 2, and 3
TNFα signaling to lipolysis	Involves cell death–inducing DNA fragmentation factor alpha-like effector A	Involves Gi proteins
De novo fatty acid synthesis	Little in mature fat cells	Marked in mature fat cells
Cell death–inducing DNA fragmentation factor alpha-like effector A	Important for lipid metabolism	Not expressed

be reesterified. There are also alternative pathways for triglyceride synthesis in fat cells, but they are quantitatively less important in humans. Glucose can be metabolized to fatty acids (*de novo* lipogenesis), and other metabolites such as pyruvate can be converted to glycerol (glyceroneogenesis). The glycerol molecules can be directly phosphorylated to alpha glycerol phosphate and used for fatty acid esterification. The major regulator of the adipocyte lipid synthesis is insulin. The hormone activates lipoprotein lipase and stimulates fat cell uptake and metabolism of glucose. Insulin may also directly stimulate the enzymes involved in fatty acid esterification. Following food intake, insulin levels are elevated, and the different regulatory factors described above are activated. During food deprivation, insulin levels are low and, consequently, the triglyceride accumulation in fat cells diminished. Obesity *per se* is associated with increased activity of lipoprotein lipase, which may facilitate net storage of triglycerides in fat cells.

Regulation of Lipolysis

KEY POINTS

- The quantitatively most important factor for lipid storage within fat cells is uptake and esterification of fatty acids derived from triglyceride-containing particles in the circulation. In addition, uptake of free fatty acids originating from the circulation or derived from fat cell lipolysis is also important. However, *de novo* lipid synthesis from glucose (lipogenesis) is only a minor contributor to total lipid storage in fat cells.

The signal and metabolic pathways regulating lipid mobilization are well recognized but subject to important species differences (Table 23.3). The regulation in human fat cells is depicted in Fig. 23.4. Triglycerides are stepwise broken down during a process termed lipolysis.[67] A specific lipase termed adipose triglyceride lipase (ATGL) and its cofactor truncated abhydrolase domain–containing protein-5 (CGI-58) catalyzes the breakdown of triglycerides into diglycerides and fatty acids. The diglycerides are hydrolyzed to monoglycerides and fatty acids by another enzyme, hormone-sensitive lipase (HSL). Finally, monoglyceride lipase catalyzes the final lipolysis step, namely formation of glycerol and fatty acids from the breakdown of monoglycerides. Despite being a relatively simple process, lipolysis is regulated in different manners by several hormonal and metabolic factors.[68,69] Five different signal transduction systems have been described, all using specific cell surface receptors. A lipolytic and an antilipolytic system are coupled to cell membrane–bound adenylyl cyclase via inhibitory G_i- and stimulatory G_s-coupled membrane proteins. Catecholamines are the most important hormones causing lipolysis stimulation, which occurs through beta-adrenergic receptors (in humans mainly type 1 and 2) and G_s-coupled proteins. However, they can also bind to alpha2A adrenergic antilipolytic receptors, which are coupled to G_i. Therefore, the net effect of catecholamines on lipolysis is determined by the balance between beta (usually dominant) and alpha effects. Other antilipolytic G_i-coupled hormones and metabolites are adenosine, prostaglandins, and lactate, which are produced locally and therefore act in a paracrine/autocrine fashion. The physiological role of these regulators is not well understood. G_s activation stimulates adenylyl cyclase, which increases the production of cyclic adenosine monophosphate (AMP) from adenosine triphosphate (ATP) and, in turn, activates an enzyme complex termed protein kinase A. Inhibition of adenylyl cyclase has the opposite effect. This mode of action also operates for two other endogenous substances, niacin and beta-hydroxybutyrate. They share the same G_i-coupled receptor, HCA2. Binding of the agonists to the fat cell surface receptors inhibits lipolysis through the described inhibitory pathway. Another class of prolipolytic hormones is the family of natriuretic peptides, which bind to cell surface receptors linked to cell membrane-associated guanylyl cyclase. This generates cyclic GMP which, in turn, activates the enzyme complex protein kinase G.

Insulin is the most important antilipolytic hormone. After receptor binding it activates receptor-associated proteins termed insulin receptor substrates. They activate the enzyme phosphoinositide 3-kinase and further downstream signaling, which ultimately stimulates the enzyme phosphodiesterase 3B. This hydrolyzes cyclic AMP into inactive 5’ AMP so that protein kinase A becomes less active. Protein kinase A and G have the same effects on the lipases discussed earlier. Thus, both kinases phosphorylate and activate HSL, as well as the ATGL–CGI-58 complex. In addition, a lipid droplet coating phosphoprotein, perilipin-1, is phosphorylated, which allows the lipases to access the lipid droplet surface for triglyceride hydrolysis.

In addition to the hormone-regulated pathways described earlier, a signal pathway through TNFα is important for controlling the chronic (basal) lipolytic activity. The cytokine is produced by fat cells and inflammatory cells within adipose tissue and is thus an autocrine/paracrine factor. The TNFα receptor signal pathway has two actions. Firstly, it inhibits phosphodiesterase 3B, which elevates the cyclic AMP level. Secondly, it activates another lipid droplet coating protein called cell death–inducing DNA fragmentation factor alpha-like effector A. Both cytokine effects increase basal lipolytic activity.

Although not definitively proven, changes in lipolysis are likely to have a clinical impact. Perhaps the most obvious factor is the relation to fat cell size.[70] The rates of spontaneous and catecholamine-stimulated lipolysis are increased, while the antilipolytic effect of insulin is decreased, in large fat cells. This may be because large fat cells contain more cyclic AMP than small ones. Obesity is often characterized by large fat cells, which would intuitively cause increased lipolysis rates. However, the impact of obesity on lipolysis is complex. The basal rate is elevated, probably as a consequence of inflammation and thereby enhanced local production of tumor necrosis factor alpha. The antilipolytic effect of

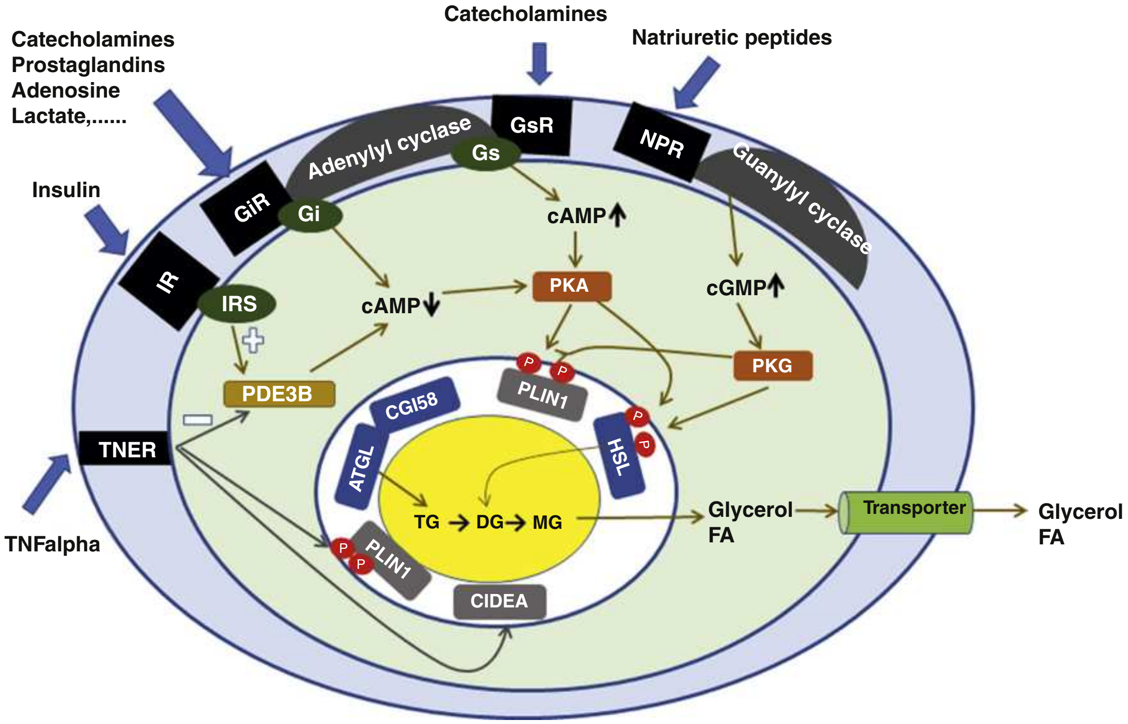

Fig. 23.4 Regulation in Human Fat Cells.

insulin is decreased, but the same is true for the prolipolytic effect of catecholamines and natriuretic peptides. The effects of excess body fat on lipolysis-regulating hormones may explain why fasting circulating fatty acid levels are only modestly elevated in the obese state. On the other hand, animal studies and short-term clinical studies show that inhibition of lipolysis improves insulin sensitivity.[71] It is therefore plausible that obesity leads to increased availability of fatty acids, which, in turn, contributes to insulin resistance, impaired insulin secretion, and ultimately type 2 diabetes according to mechanisms described in detail elsewhere.[71] On the other hand, prospective studies, which are needed to support a causal role of lipolysis in metabolic diseases, are rare. In one such study it was found that increased basal lipolysis and decreased catecholamine-induced lipolysis predict future glucose intolerance and body weight gain.[72] The failure of insulin to adequately suppress fatty acid levels in obesity may also lead to so-called metabolic inflexibility in skeletal muscle.[73] The utilization of glucose and fatty acids as fuels for skeletal muscle is switched towards fatty acid use, which may cause lipid toxicity, and thereby insulin resistance, as discussed in detail elsewhere.[73] Finally, an association between fat cell lipolysis *in vitro* and circulating lipid levels has been demonstrated in cross-sectional studies.

KEY POINTS

- In human fat cells, only a few hormone systems have a pronounced, acute effect on lipolysis: the stimulatory catecholamines and natriuretic peptides, plus the inhibitory insulin. In addition, the spontaneous (basal) lipolysis is regulated by local inflammatory factors, in particular TNFα, which increases the lipolytic rate. In obesity and other metabolic conditions, lipolysis regulation is altered. Humans with excess body fat have increased basal lipolysis, decreased ability to activate lipolysis by catecholamines, and resistance to the antilipolytic effect of insulin. Together, these alterations are involved in the metabolic complications of obesity, such as dyslipidemia and insulin resistance. Prospective studies suggest that altered fat cell lipolysis is a factor behind future body weight gain and glucose intolerance.

Glucose Metabolism

Fat cells use the same signal system and regulation as skeletal muscle for glucose metabolism. In both cell types, insulin is the major regulatory hormone (stimulation of uptake and further metabolism). However, in quantitative terms, white adipose tissue has a much smaller capacity than skeletal muscle to handle a glucose load. Approximately 10% to 15% of glucose dispersal after food intake is into adipose tissue. There is, on the other hand, one important exception as regards the quantitative role of fat cells in carbohydrate metabolism, namely lactate.[74] As a result of glucose metabolism, fat cells produce large amounts of lactate, and this is augmented in large fat cells in obesity. The latter might be due to decreased oxygenation in obese adipose tissue and/or changes in cellular metabolism leading to activated glycolysis (see earlier). Lactate serves as an autocrine inhibitor of lipolysis (Fig. 23.4). In addition, adipose tissue provides a source for circulating lactate to be used as three-carbon fuel.

KEY POINTS

- Adipose tissue plays a quantitatively minor role in the regulation of whole-body glucose uptake. However, glucose metabolism in fat cells has many indirect effects on carbohydrate metabolism, such as on lactate turnover and insulin sensitivity.

Summary

Adipocyte storage and release of energy-rich fatty acids is essential for survival during long periods of food deprivation and in connection with long-term physical exercise. In addition to being an energy storage organ, white adipose tissue is a reservoir for lipids that may be toxic in other places such as liver, pancreatic β cells, and skeletal muscle. Having too much or too little adipose tissue alters lipid handling and leads to disturbed metabolism, where insulin resistance is the most prominent and important dysfunction.[75] Enlarged fat cells and unfavorable adipose distribution into the upper body/visceral areas are major culprits in this scenario, and altered lipolysis probably the primary pathophysiological factor.

HUMAN BROWN ADIPOSE TISSUE—BROWN OR BEIGE?

Brown adipose tissue (BAT) is primarily found in small mammals and hibernating animals, and brown adipose cells in mice have the same origin as muscle cells.[76] BAT regulates body temperature through nonshivering thermogenesis and becomes activated when the animals are exposed to cold or temperatures below their thermoneutrality zone. In mice this is around 30°C, when metabolism is the lowest, and thus considerably higher than the usual room temperature at which mice are housed. Exposure to cold leads to activation of the sympathetic nervous system, which increases lipolysis and the release of fatty acids that are used by the mitochondria-dense brown adipose cells. Increased sympathetic activation and lipolysis in BAT increase nonshivering heat production through the UCP1 uncoupling protein in the mitochondria. UCP1 uncouples the mitochondria to produce heat rather than the normally generated ATP.[77] Many experiments in animals have also shown that sympathetic activation of BAT in the cold consumes enough calories to reduce the amount of adipose tissue, and thus could be a target to treat obesity.

BAT is not only present in small mammals, but also in the interscapular region in human infants, where it is critically important for thermogeneration during the first year of life. It then gradually disappears over the first decade. It was long considered to be completely absent in adult humans, with a few exceptions, including patients with pheochromocytomas secreting high amounts of catecholamines and outdoor workers chronically exposed to cold environments. However, in 2007 it was suggested that adult humans may also have some smaller BAT depots.[78] This provoked new scientific interest, and, in 2009, several clinical studies using advanced positron emission tomography/computed tomography scans documented the presence of distinct adipose depots in adult humans that were functional and increased glucose and fatty acid uptake, as well as thermogenesis, following stimulation with β3-adrenergic stimuli or exposure to cold. However, these putative BAT depots were small (around 50–100 g) and primarily found in the cervical, supraclavicular, axillary, mediastinal, paraspinal, and abdominal regions around the kidneys. These findings were followed by many studies suggesting that individuals with larger amounts of BAT also had lower body weights; i.e., it was hypothesized that increasing BAT could be a way of treating obesity. However, several studies performed since then have concluded that BAT in adult humans is not the same BAT observed in rodents, with small lipid droplets and high amounts of mitochondria and UCP1 protein. Instead, it was suggested that human BAT is more of a so-called “beige/brite” phenotype with large lipid droplets and low UCP1 expression, and is of unclear importance as a temperature regulator.

This has been an issue of long debate, but recent analysis suggests that human BAT is, in fact, similar to the animal tissue, but with a different morphology, because humans live in a thermoneutral temperature and are well insulated and, therefore, do not normally require sympathetic activation and BAT-induced regulation of thermogenesis.[79] Although this may be the case, it is still not likely that human BAT is large enough, contains sufficient UCP1, and/or can be activated to the extent required to actually be a target for body weight reduction. This is clearly in contrast to BAT in mice and other animals.

Brown versus Beige/Brown Adipose Cells

As discussed, human brown adipose cells have been characterized as intermediate between white and brown cells, and therefore named beige/brown cells. However, administration of lipolytically active β3-agonists was shown to increase metabolism in BAT in humans, although only at very high amounts, when β3-selectivity was unlikely and associated with increased heart rate and blood pressure.[80] This would not be acceptable for an agent to treat obesity. It is well-established that β3 receptors are important for activating BAT in mice, but further studies have shown that β2-adrenergic receptors responding to noradrenaline are mainly expressed in humans. In fact, β3 receptors do not seem to be expressed in human BAT cells at all. However, they are highly expressed in human urinary bladder and gall bladder, as well as in some areas in the heart, which can explain the increased heart rate and blood pressure seen with the administration of β3-selective agonist.[80]

The small amount and different morphology of human brown adipose cells (the beige/brown phenotype) have been taken as an indication that the tissue also is thermogenically unimportant. However, it has also been argued that the reason for this is that humans normally live in well-insulated, thermoneutral environments. In support of this, murine cells also become less active when the animals live in a thermoneutral environment for mice, i.e., around 30°C. Nevertheless, the amount of BAT in man is so small that it is unlikely that it could be activated to a sufficient extent to treat obesity, even if we had access to drugs that could specifically activate human BAT cells. Providing indirect support for this is that fact that the antidiabetic PPARγ agonists, the TZDs, induce beige/brown cells and UCP1 in human adipose cells.[81] However, treatment with TZDs is known to increase body weight, rather than decrease it, supporting the idea that human brown cells are a difficult obesity target.

Beige/Brown Adipose Cells in the Subcutaneous White Adipose Tissue—A Possible Target in Obesity?

Another scientific approach to find ways to increase oxidative capacity and thermogenesis in human adipose tissue is to increase mitochondria and UCP1 in the conventional white adipose cells through partial transdifferentiation of white cells to a beige/brown oxidative phenotype or to target available specific progenitor cells to become beige/brown and increase their oxidative capacity. It seems that both approaches may be possible, but a key question is if enough UCP1 can be induced to actually increase thermogenesis of sufficient magnitude to also reduce obesity in humans; this remains to be demonstrated. However, both in rodents and in humans, white adipose cells in the large SAT are susceptible to partial transdifferentiation to a beige/brown phenotype. TZDs can induce a beige/brown phenotype in white SAT cells. Mechanistically, this is due to sirtuin-dependent deacetylation of PPARγ promoting its interaction with PRDM 16 and EBF 2, leading to its binding to brown-specific enhancers. In addition to TZDs, thyroid hormones, FGF 21, and BMP4, 7, 8b, and 9 have been shown to increase beige/BAT, and TZDs and BMP4 also target human white adipose cells.[79,82]

Thus, the white subcutaneous adipose cells are quite susceptible to undergoing partial transdifferentiation from a white to a beige/brown phenotype, but the number of cells capable of being transdifferentiated and the overall consequences for thermogenesis and body weight reduction need to be demonstrated in humans. It has been shown that increased BMP4 levels in mice induce a beige/brown and oxidative phenotype of the white adipose tissue of sufficient magnitude to increase energy expenditure and prevent induction of obesity.[83] However, whether these findings can be translated to a possible therapeutic target in humans is currently unclear, considering the complex BMP signaling pathways and potential side effects.

It is clear that the quantity of induced beige/brown adipocytes required to increase energy expenditure is considerably higher than that required by normal and functional BAT. Considering that the UCP1 mRNA levels are around 1000-fold higher in brown than in white adipose cells, it has been calculated that a relevant browning agent needs to raise the amount of UCP1 in white adipose tissue by 10-fold in order to have around 1% of the amount in BAT.[84] Although the pharmaceutical industry is trying to develop browning agents suitable for humans, no such agent is currently available, and it is not clear if this will become a possibility.

KEY POINTS

- Brown adipose cells are present in small amounts in humans and are characterized by large lipid droplets and being more beige/brite than brown. Unlike murine cells, they only have small amounts of UCP1 and mitochondria. Although they respond to sympathetic activation, it is unlikely that they can increase metabolism to an extent needed to reduce body weight.

Aging Reduces Brown and Beige Adipose Cells

Aging is associated with profound changes in most organs and tissues, including BAT in both rodents and humans.[79] This reduction in BAT is more likely to have consequences for thermogenic regulation and propensity to increase body weight in animals than in humans.

It has also been shown that the number of beige/brown cells in the white adipose tissue in rodents and humans decrease with age, probably as a consequence of both cell senescence and reduced sympathetic activity. Thus, aging contributes to the loss of both BAT mass and number of beige/brown cells.

Summary

BAT is essential for energy homeostasis in rodents. The tissue is present in humans as well, but appears less important from a physiological and pathophysiological point of view. Thus, it is doubtful if human BAT can be used as a target for treating obesity and its comorbidities.

ADIPOSE TISSUE ENDOCRINE FUNCTIONS AND CHANGES IN OBESITY

It was already well-established in the 1960s that white adipose tissue releases glycerol, fatty acids, lactate, and perhaps some less abundant lipid species into the circulation. The pathophysiological role of these factors is described in detail under the lipid turnover section. In contrast, the endocrine function of adipose tissue and release of peptide factors and hormones, collectively termed “adipokines,” long remained unknown. Admittedly, parabiosis experiments in the 1950s using wild-type and severely obese *ob/ob* mice suggested that there was an adipose-derived satiety signal impacting on food intake. However, it was not until 1994, when leptin was cloned, that adipose tissue began to be considered a true endocrine organ.[76] Leptin is a peptide hormone belonging to the cytokine family and is primarily released from adipocytes in direct proportion to fat mass. One of its main actions is to attenuate hunger signals in the hypothalamus, and it therefore has a true endocrine function. Leptin is the gene that is disrupted in *ob/ob* animals, and leptin administration effectively normalizes food intake and body weight in animal models. Big clinical hopes were therefore put on leptin as a treatment modality in common forms of obesity. Unfortunately, leptin levels are very high in people with obesity, and the response to exogenous leptin is nonsignificant, possibly due to “leptin resistance.”[85] Leptin missense mutations are uncommon in humans but have been reported in a few families around the world. This results in massive obesity in early childhood, and in these cases recombinant leptin administration (metreleptin) is very effective. Leptin is also used in rare lipodystrophic conditions (with low circulating levels) and is believed to exert its action by reducing food and lipid intake, thereby normalizing the hypertriglyceridemia associated with these conditions.[86] More recently, metreleptin therapy has also been suggested for other leptin-deficient states, including anorexia nervosa.[87]

KEY POINTS

- Leptin remains, to date, the best characterized adipokine with a classical endocrine mechanism of action. While it does not display any relevant effects in the treatment of common forms of obesity, it has an important therapeutic role, particularly in rare forms of leptin deficiency.

The identification of leptin sparked an intense search for additional factors released by adipose tissue. Adipose tissue expresses up to one third of the proteins encoded by the genome, and this includes several hundred potentially secreted proteins. Proteomics screens of different human and murine adipocytes/adipose tissue systems have collectively identified greater than 600 released peptides/proteins.[88] This does not imply that all are actively secreted, as some factors may be released through cell necrosis/apoptosis or just under the culture conditions used *ex vivo*. Peptide factors released from adipose tissue include cyto-/chemokines (discussed in the immunometabolism section), growth factors (e.g., TGFβ), angiogenic factors (e.g., vascular endothelial growth factor), blood pressure regulators (e.g., angiotensinogen), and structural proteins (e.g., collagens). Importantly, with the exception of leptin and adiponectin (discussed later), very few of these “adipokines” are specific for adipose tissue, and most are expressed in several other organs. Furthermore, in addition to peptides/proteins, adipose tissue releases a large set of nonpolar and polar metabolites, apart from fatty acids, sphingolipids, and prostaglandins; these include, e.g., amino acids, lactate, and nitric oxide.[89] The role of some of these factors is briefly discussed later, but it is not possible to cover everything that is released/secreted from adipose tissue. This section will therefore highlight some of the most well-studied adipokines, which are also summarized in Table 23.4. Among these is adiponectin, a protein belonging to the complement factor family that is secreted almost exclusively from adipocytes. Adiponectin was cloned by several different groups shortly after the discovery of leptin and is secreted as a tri-, hexa-, or multimeric complex. It is now generally thought that the multimeric complex is the biologically active form and that it binds and activates two distinct receptors, AdipoR1 and AdipoR2, which display the highest expression in liver and skeletal muscle.[90] Adiponectin is released into the circulation, and is therefore considered an endocrine hormone, but in contrast to many other factors secreted from adipose tissue, the levels decrease with increased fat mass and insulin resistance. Adiponectin levels are therefore considered a good marker of metabolic risk. However, despite almost 25 years of research, the pathophysiological role of adiponectin in humans remains unclear, and most studies have been performed in murine models. In rodents, adiponectin improves insulin sensitivity, normalizes adipose tissue lipolysis, reduces hepatic gluconeogenesis, and increases skeletal muscle glucose uptake and fatty acid oxidation.[91] Despite these interesting effects, it has proven very difficult to translate this into efficient therapies in humans. Whether this is due to the complex structure of biologically active adiponectin, that it is more difficult to efficiently activate adiponectin receptors in humans, or that it simply plays another role in humans versus rodents is not clear.

Leptin and adiponectin remain to date the only true endocrine adipokines, i.e., factors released from the adipose tissue and exerting

TABLE 23.4 Adipokines

Factor, Main Function	Most Important Effects	Pathophysiology (Changes in Obesity)	Main Cellular Source in Adipose Tissue
Free fatty acids, endocrine factors	Increase very low density lipoprotein; gluconeogenesis; reduce glucose uptake in skeletal muscle; effects on insulin secretion?	Increased release primarily through non–hormone-stimulated lipolysis, reduced antilipolytic sensitivity to insulin contributes	Adipocytes
Leptin, endocrine factor	Reduced appetite; increased fatty acid oxidation; plays a role in reproduction	Increased release, primarily from subcutaneous depots; leptin resistance in obesity	Adipocytes
TNFα, autocrine or paracrine factor	Stimulates lipolysis and inhibits insulin action in fat cells	Increased	Macrophages and possibly other cells in the stroma vascular fraction
CCL2, paracrine factor	Chemoattractant factor that stimulates macrophage infiltration	Increased	Fat cells, immune cells, and other cells in the stroma vascular fraction
Adiponectin, endocrine factor	Protective against many pernicious metabolic effects	Reduced	Adipocytes
Interleukins, IL1-beta, IL6, and IL8, paracrine factors	Unclear role; promote an inflammatory role and may attenuate insulin signaling	Increased	Fat cells, immune cells, and other cells in the stroma vascular fraction
Acylstimulating protein, paracrine factor	Stimulates lipid deposition; attenuates fatty acid release	Increased	Fat cells, and other cells in the stroma vascular fraction
Plasminogenactivatorinhibitor-1, endo-, paracrine factor	Promotes thrombosis	Increased	Cells in the stroma vascular fraction
Visfatin, paracrine factor	Regulates inflammation	Increased	Macrophages
Osteopontin	Regulates inflammation	Increased	Fat cells, immune cells, and other cells in the stroma vascular fraction

KEY POINTS

- Adiponectin is well-studied, particularly in rodent models, where it plays important roles in regulating insulin sensitivity. However, its therapeutic role in humans remains unclear, and its druggability is hampered by the large size of the biologically active multimeric complexes.

effects through distinct receptors in another organ. Retinol-binding protein-4 (RBP4) is released from adipose tissue and is present at higher levels in the circulation of people with obesity/insulin resistance. RBP4 is a biomarker for insulin resistance and cardiometabolic risk, but to date an established mechanistic link has not been identified.[18] Virtually all other adipokines released from adipose tissue are believed to act locally in an auto- or paracrine fashion. Among these are, e.g., acylstimulating protein (ASP, also termed C3adesArg), plasminogen activator inhibitor-1 (PAI1), visfatin (also termed pre B-cell colony-enhancing factor [PBEF] or nicotinamide phosphoribosyltransferase [NAMPT]), and osteopontin, to name a few.

ASP is formed by enzymatic cleavage of the precursor protein C3 into C3a, initiated by the enzymes adipsin and factor B. ASP seems to play a role in triglyceride synthesis and hydrolysis, and increases fatty acid esterification and inhibits fatty acid release. The function of ASP is considerably attenuated in familial combined hyperlipidemia, although the mechanisms are not yet understood. A caveat in studying ASP is that rodents do not express relevant parts of the ASP system in adipose tissue, which has hampered further investigations.

PAI1 is a prothrombogenic factor released from several tissues, including adipose tissue, and the levels are increased in the obese state. As discussed elsewhere, it is also a marker of cellular senescence, and it has been speculated that it could play a role in linking obesity to cardiovascular complications.

Visfatin, which is identical to the previously described proteins PBEF and NAMPT, is an enzyme originally described as deriving from visceral fat macrophages. However, visfatin is also expressed in other organs, including muscle and liver. The expression of visfatin is associated with tissue inflammation and a pernicious metabolic profile, as well as atherosclerosis, but the casual links and the role of adipose tissue remain unclear.[92]

Osteopontin is a glycophosphoprotein expressed in several different cell types, including osteoblasts/osteocytes, where it is involved in bone metabolism and remodelling.[93] However, it is also expressed in adipose tissue, where it is believed to regulate the secretion of proinflammatory cytokines from different immune cells. Plasma concentrations of osteopontin and osteopontin mRNA in adipose tissue are upregulated in obesity and insulin resistance. Similar to many other adipokines, the causal role remains to be established.

Summary

White adipose tissue expresses at least two adipokines (leptin and adiponectin) with a clear endocrine function, in that they target other organs/tissue via specific receptors. Several other factors are released and present in the circulation, but these are not unique to adipose tissue *per se*, and the contribution to the circulating concentrations versus other peripheral organs is not yet clear. The latter can only be determined by comparing arteriovenous differences in vessels going to and from different tissues using clinical techniques that only very few groups in the world can perform. In some cases the receptors or signaling mechanisms of these adipokines remain to be elucidated. Most of the adipokines released from adipose tissue are believed to act locally and seem to play important roles in determining tissue function and lipid storage capacity. Obesity perturbs the expression of adipokines and in most cases leads to an increase in the expression of, e.g., leptin, proinflammatory proteins, and extracellular matrix genes.

TABLE 23.5 Adipose Tissue–Targeted Therapies for Human Obesity and its Comorbidities in Current Use

Treatment	Action
Restricted energy intake	1. Reduce adipose mass 2. Bariatric surgery long-term effective 3. Metabolic effect related to decrease fat cell size
Surgical removal of adipose tissue	1. Omentectomy has metabolic effects in connection with gastric banding, but not together with gastric bypass 2. Abdominal subcutaneous liposuction has no metabolic effects
Activation of brown adipose tissue	1. No important effect on body weight 2. Small metabolic effects
Glucagon-like peptides	1. Primarily used for diabetes treatment 2. Reduce body weight, sometimes effectively, and are currently used for this purpose. Probably have an indirect effect on adipose tissue
Thiazolidinediones	3. Increased subcutaneous adipose lipid storage causing decreased fatty acid levels 4. Antidiabetic, but risk of important side effects such as weight gain
Other antidiabetic agents	1. Biguanides may lead to some weight reduction 2. Sodium-glucose cotransporter 2 inhibitors may cause modest weight reduction 3. Probably indirect effects on adipose tissue
Nicotinic acids	1. Antilipolytic causing improved lipid profile but no change in body weight 2. May cause glucose intolerance
Endurance training	1. Enhances catecholamine-induced lipolysis 2. Long-term effects on body weight and metabolism are unknown
Leptin	1. Decreased appetite. Increased energy expenditure 2. Not effective in common obesity
Antibodies against TNFα	1. Neutralizing adipose inflammation 2. No clear effect on diabetes or insulin sensitivity 3. Body weight neutral

The exception to this rule is adiponectin, which is one of the few adipokines negatively regulated by increased fat mass. As mentioned, the role of different locally released metabolites is not discussed herein, but it is interesting to note that several of them (e.g., lactate, succinate, and beta-hydroxybutyrate) have been shown to bind and activate G-protein coupled receptors, which are expressed on both adipocytes and immune cells.[94] This implies that the number of “adipokines” could be substantially higher than what has so far been appreciated. Moreover, the levels of several amino acids (e.g., glutamine, branched-chain amino acids) and their derivatives (e.g., kynurenic acid) are altered in the obese state and impact adipose tissue function via both epigenetic (see immunometabolism section) and receptor-mediated pathways. This area of research is therefore still very active, and novel insights are reported continuously.

ADIPOSE TISSUE AS A THERAPEUTIC TARGET

Bearing in mind the multiple actions of adipose tissue, numerous site-directed therapeutic modalities are possible and have been tested in animal models. Those tried in human obesity and its comorbidities will be discussed and are summarized in Table 23.5. The most obvious approach is to decrease fat mass by means of reduced energy intake. Different diets have been publicly available since Banting published a formula based on reduced intake of carbohydrates and starch in 1863.[95] A weight reduction of 5% or more usually leads to metabolic improvements, which could be further boosted in combination with enhanced physical activity. However, no diet is known to exert long-term effects on obesity remission in the general population.[95] In fact, often the end result is higher body weight compared with the weight before starting the diet (“yo-yo” effect). In contrast, bariatric surgery leads to long-term reduction in fat mass and is accompanied by positive effects on diabetes incidence/remission, mortality, and several other obesity complications.[96] There are different surgical procedures. Earlier techniques are technically easier but result in less marked weight loss. The most common current operation procedures, such as gastric bypass and sleeve gastrectomy, are much more effective in terms of weight loss and are also sufficiently safe.[97] After an initial and marked weight loss, body weight increases gradually to a new long-term steady state, which is approximately 25% below the preoperative body weight. The mechanism behind the beneficial effects of body weight loss are not well understood but are likely to be multifaceted. Improved insulin sensitivity is linked more closely to diminished fat cell size than reduced fat mass *per se*.[98] In theory, surgical removal of adipose tissue is an attractive antiobesity therapy. However, large amounts adipose tissue cannot be safely removed, due to immediate and long-term risks of severe complications. Therefore, selective pernicious adipose areas that are relatively easy to remove have been taken out since the turn of the last century. The major omentum has been removed in connection with bariatric surgery.[99] Positive effects were reported in connection to gastric binding but with gastric bypass. The reason for this difference might be the stronger effect on weight reduction of the latter surgical procedure. Liposuction is often used for cosmetic surgery, but removal of approximately 10 kg of abdominal SAT in obesity had no effect on the cardiometabolic risk profile, on either a short- or long-term basis.[100]

KEY POINTS

- So far bariatric surgery is the only proven effective means of reducing body weight for a long time in subjects with common forms of obesity. Even modest reductions in body weight have a positive effect on metabolic obesity complications. The ameliorating effect of weight reduction is not likely to be due to diminished fat mass *per se*. Instead, the reduced fat cell volume is likely to play such a role.

Pharmacotherapy in Obesity

The approved antiobesity medications are covered in another chapter. Herein only adipose-specific therapies are discussed in some detail. Although many pharmacological agents have been tried, usually as a means to suppress appetite, most have been withdrawn from the market or are no longer used due to side effects.[101] These agents act centrally, and are thus not important for fat cell–mediated actions. Glucagon-like peptide 1 receptor agonists have been shown to induce long-term, and in some cases marked, body weight reduction. Although receptors for the hormone are present in human fat cells and cause metabolic effects, they cannot be linked to effects on body weight. Biguanides may also reduce body weight, but the effect is usually modest (circa 3%). Although metabolic/endocrine effects on human adipose tissue are described, they are not important for the effect on body weight, and they are not approved for weight reduction

Activation of BAT through stimulation with beta-3 adrenoceptor agonists has been tested clinically.[102] This issue was thoroughly discussed earlier.

TZDs are enhancers of insulin sensitivity and have been used to treated type 2 diabetes in obese/overweight patients.[103] Much of their antidiabetic effect is caused by activation of the nuclear receptor PPARγ in fat cells. This leads to retention of lipids, predominantly in SAT, and consequent lowering of circulating fatty acid levels, which, in turn, improves insulin action/secretion. However, these agents currently have limited use due to side effects such as weight gain (due to hyperplastic expansion of SAT), fluid retention, osteoporosis, and (at least for older agents) adverse cardiac events.

Nicotinic acid and its derivatives have long been used to treat hypertriglyceridemia, which often accompanies obesity.[104] One mechanism is through inhibition of fat cell lipolysis so that fewer fatty acids are delivered to the liver for synthesis of very low density lipoproteins. These drugs are body weight–neutral but may cause glucose intolerance, and they have been withdrawn from the market due to side effects.

The effects of exercise training on human adipose tissue function has been studied for many years.[105] If not compensated by increased energy intake, some body weight loss can be expected. Several exercise effects on adipose endocrine and metabolic functions, as well as on inflammation, have been reported. Most promising from a therapeutic point of view is that endurance training induces a long-term increase in the lipolytic effect of catecholamines. However, long-term effects of enhanced physical activity alone on body weight and metabolic profile are not documented.

As regards endocrine function and inflammation, only leptin and TNFα have been intensely investigated in humans to date.[90,106] These therapies were discussed thoroughly earlier.

KEY POINTS

- In theory, a number of fat cell–specific regulatory factors such as adipocyte differentiation, beta oxidation, lipolysis, and the endocrine functions are potential pharmaceutical targets for combatting obesity and dysregulated metabolism. So far, this therapeutic area is not very advanced; the only important exception hitherto are leptin and thiazolidinediones.

Summary

Other than bariatric surgery, no alternative adipose-targeted therapies have so far demonstrated clear-cut and long-term effectiveness in the treatment of obesity and its comorbidities in the general population. It is possible, though, that agents and their analogs derived from the gastrointestinal tract can be used as fruitful alternatives to bariatric surgery. Some important targets according to mouse models, such as adiponectin and hormone-sensitive lipase, have not yet been tested in humans. In the future, gene therapy might be useful. For example, several long noncoding RNAs are fat cell–specific and functional, and could be useful tools to improve fat cell function.[107]

KEY POINTS

- Lipodystrophy syndromes are a heterogeneous group of disorders characterized by complete or partial lack of adipose tissue in certain areas of the body, with excess of adipose tissue elsewhere.
- The etiology of lipodystrophy may be either a congenital or acquired and involves a loss of mature, functional adipocytes associated with failure of adipogenesis, adipocyte apoptosis, or storage of triglycerides.
- Congenital lipodystrophy is caused by abnormal gene activations and signaling that impair adipocyte differentiation, whereas acquired lipodystrophy is most commonly observed in patients with human immunodeficiency virus who are receiving highly active antiretroviral therapy.
- Metabolic complications, such as insulin resistance, dyslipidemia, hepatic steatosis, endovascular inflammation, and oxidative stress, are associated with lipodystrophy syndromes and constitute major comorbidities of these syndromes.
- Current treatments such as metformin, thiazolidinediones, growth hormone replacement, growth hormone–releasing hormone analogs, and US Food and Drug Administration–approved recombinant leptin therapy may help with clinical features and associated metabolic complications of lipodystrophy.

LIPODYSTROPHIES: DEFINITION AND DIAGNOSIS

Lipodystrophy syndromes are a diverse group of rare clinical disorders, the central feature of which is either a congenital or acquired complete or partial lack of adipose tissue (lipoatrophy) and/or a combination of lack of adipose tissue in certain body areas, with excess of adipose tissue (lipohypertrophy) elsewhere.[1] Despite progress in identifying the genetic basis and pathways of the disease, lipodystrophy is often underestimated or misdiagnosed because of its heterogeneity and rarity. According to the most recent multi-society practice guidelines, diagnosis of a lipodystrophy disorder is based on patient's history, clinical examination, metabolic state, and body composition.[2]

Metabolic disorders, and especially a severe form of the metabolic syndrome, are also implicated in this abnormal deposition of adipose tissue that cannot be stored in the appropriate subcutaneous depots.[3] Abnormalities such as insulin resistance and its associated clinical features are present in nearly all varieties of lipodystrophies.[4] In addition, patients with lipodystrophies also manifest a group of unique features such as hypertriglyceridemia and severe mixed dyslipidemia, progressive hepatic steatosis, progression to poorly controlled diabetes, and an increased metabolic rate (Fig. 24.1).[5] Severe dysmetabolic situations associated with lipodystrophy syndromes are responsible for the increased risk of severe comorbidities and mortality in these patients.[6]

No firm diagnostic criteria currently exist, and a lipodystrophy disorder is usually recognized clinically, often based on both patients' and doctors' perceptions and assessment. A meticulous physical examination is required and can be further supported by anthropometry, dual energy x-ray absorptiometry (DEXA), computed tomography (CT), and whole-body magnetic resonance imaging (MRI).

Anthropometry, or measurement of skin folds and limb circumference, is an easy, affordable, and practical way to estimate fat loss and fat redistribution. However, its reliability is heavily dependent on the consistency and the skill of the examiner(s), and it may have poor sensitivity, especially during early stages of the disease. Objective measurement of facial lipoatrophy also poses a challenge. Serial photographs (with the patient's consent) have been used to document and compare the facial wasting over time.

DEXA, CT, and MRI scans are additional modalities that have been developed to allow direct quantification of fat within specific tissues and/or body mass, as well as fat distribution. Although all these techniques are accurate and noninvasive, they are also expensive, have limited availability, and are not cost-effective for use in everyday clinical practice. Their use, therefore, has been limited to the research field.[7]

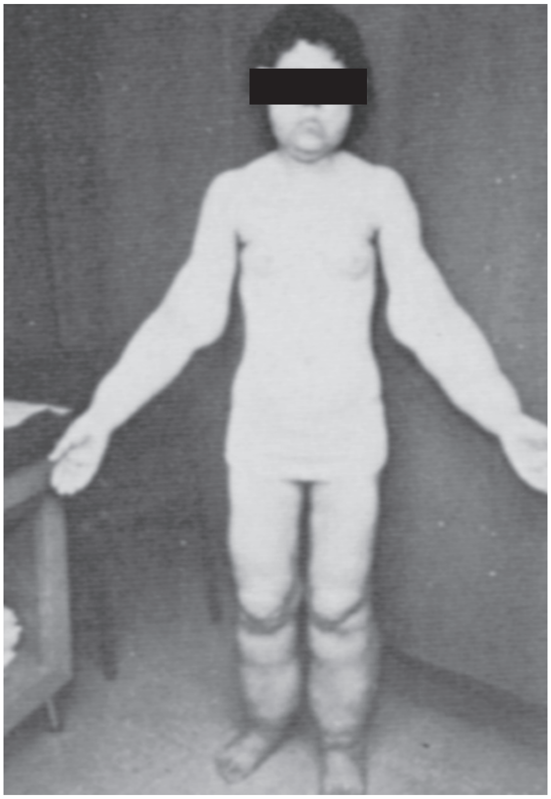

Fig. 24.1 Congenital lipodystrophy.

In the past few years, ultrasound has emerged as a promising alternative quantitative tool to assess body fat changes. Although it demonstrates good accuracy and accessibility, more studies are needed to elucidate its value and to comparatively evaluate ultrasound with other imaging modalities. Standardization of ultrasound techniques and analyses of cost-effectiveness will also be essential for its potential wider clinical applications.[8] Table 24.1 summarizes the main advantages and disadvantages of the aforementioned body composition and adipose tissue imaging techniques.

Laboratory testing and imaging are valuable tools for physicians to support their diagnosis and determine the type and severity of lipodystrophy. Patients with lipodystrophy tend to have low serum leptin levels. It should be noted that no defined serum leptin level threshold can be used to confirm or exclude the diagnosis of lipodystrophy.[2,9,10] Genetic testing is the gold standard and may assist in clinical diagnosis confirmation.[11] However, because of limited resources and DNA sequencing availability, the current recommendations suggest that genetic testing should only be considered in suspected familial lipodystrophies and at-risk family members.[2] It should be underlined that negative genetic tests cannot rule out the presence of a genetic lipodystrophy syndrome.

PATHOPHYSIOLOGY OF LIPODYSTROPHY

In previous decades, the study of mechanisms underlying lipodystrophy has attracted significant attention, to a certain extent owing to the interest of the scientific community in obesity research. It is now recognized that white adipose tissue is not an inert storage depot organ but an active endocrine organ that plays a critical role in regulating energy homeostasis and mediating inflammation.[12] Because there are common features in the etiopathogenesis of lipodystrophy and obesity, lessons learned from studies of the lipodystrophies may provide essential information not only for the management of these rather rare cases, but also for obesity research and management.

Much of our knowledge regarding the mechanisms underlying the pathogenesis and manifestations of lipodystrophies has been obtained

TABLE 24.1 **Advantages and Disadvantages of Different Body Composition and Adipose Tissue Imaging Techniques**

Ultrasound	Dual Energy X-Ray Absorptiometry	Computed Tomography	Magnetic Resonance Imaging
Advantages			
No radiation exposure Safe for repeated measurements Satisfactory reliability Easy to operate Portable and easily available Low cost	Low radiation exposure Well tolerated for repeated measures High accuracy and precision Information on total and regional percentage of fat Information on fat and fat-free mass Moderate cost	High accuracy and precision Information on specific body fat compartments Assessment of subcutaneous and visceral fat and fat-free mass	No radiation exposure Safe for repeated measurements High accuracy and precision Information on specific body fat compartments Body mass composition differentiation, assessment of subcutaneous and visceral fat
Disadvantages			
Low accuracy Interpretation is more difficult, subjective, and affected by excessive edema Experience-related No validated procedure or clinical protocols	Moderate cost Not portable Radiation exposure (even low) Hard to distinguish subcutaneous and visceral fat Interpretation is affected by fat-free mass hydration status and body thickness Experience-related Variability among different versions and manufacturers	High cost Not portable Limited availability Radiation exposure Need for specific software (for fat-free mass) and technical skill for image analysis	High cost Not portable Limited availability Requires specific software Long scan duration

through mouse studies and as a result of human genome sequencing. It is now understood that patients with lipodystrophy have primarily a loss of mature, functional adipocytes, as opposed to an absence of lipids in otherwise normal adipocytes.[13,14,15] The underlying defects could be associated with failure of adipogenesis, adipocyte apoptosis, or a failure to store triglycerides in existing adipocytes because of ineffective lipogenesis or excessive lipolysis.[16] Differentiation of adipocytes is controlled by a variety of mitogenic and adipogenic gene activations and signaling pathways. Abnormal development and differentiation of preadipocytes and adipocytes, as well as increased adipocyte apoptosis, may lead to the development of a particular lipodystrophy (Fig 24.2).[16] Furthermore, the overall alterations in adiposity may result in the metabolic derangements and subsequent complications observed in patients with lipodystrophies.[17,18,19]

In this chapter, we will discuss the classifications of different types of lipodystrophies, their distinctive clinical presentations, our current understanding of the underlying mechanisms, and the recommended treatment modalities.

CLASSIFICATIONS OF LIPODYSTROPHIES AND THEIR CLINICAL MANIFESTATIONS

The classification of lipodystrophies is based on distinct clinical presentation, unique patterns of adipose tissue deficiency (namely, generalized or partial lipodystrophy), and manner of acquisition (inherited and acquired forms). Thus, lipodystrophies are categorized into four major categories: congenital generalized lipodystrophy (CGL), acquired generalized lipodystrophy (AGL), familial partial lipodystrophy (FPL), and acquired partial lipodystrophy (APL). However, lipodystrophy syndromes include additional subtypes such as the progeroid syndromes, and it is likely that this classification may become inadequate as more genetic causes and pathophysiological mechanisms associated with lipodystrophy are identified.[11]

Generalized Lipodystrophies

Generalized lipodystrophy encompasses rare but clinically striking disorders that may be congenital (Berardinelli–Seip syndrome)[20,21] or acquired (Lawrence syndrome).

Congenital Generalized Lipodystrophy. CGL, or Berardinelli-Seip congenital lipodystrophy (BSCL), was initially described in 1954 by Berardinelli in Brazil in two children, and 5 years later by Seip in Norway in three other patients.[20,21] It is a rare syndrome that inherited in an autosomal recessive manner and is observed mainly in cases of parental consanguinity or in isolated communities, probably because of "founder effect."[22] It is characterized by near-complete absence of body fat that may spare the supportive adipose tissue in the palms, soles, joints, and the area under the scalp, depending on the underlying genetic cause.[23] CGL is also associated with the early onset and progressive development of several metabolic disorders and comorbidities.[6,24] To date, it has been reported in approximately 300 patients of various ethnic backgrounds.[24-29]

Babies with CGL are noted to have an abnormal appearance owing to absence of body fat that usually arises at birth or during the first year of life, whereas some specific subtypes of CGL may become prevalent during childhood or later.[11] Adipose tissue is absent from not only subcutaneous, but also from intraabdominal sites, and the resultant prominent musculature causes a striking recognizable phenotype. MRI of the abdomen shows complete absence of intraabdominal, retroperitoneal, and subcutaneous fat, but a prominent fatty liver, as well as the presence of fat in certain anatomic sites such as the orbits, palms, and soles. Thus, this genetic defect results in poor development of metabolically active but not mechanically important adipose tissue.[10,23,30,31] Other somatic abnormalities that contribute to the abnormal appearance are acanthosis nigricans, a protuberant abdomen associated with hepatomegaly, and/or splenomegaly, hernias, prominent musculature, and acromegaloid features.[24,27]

Apoptotic adipocyte material

Fig. 24.2 Differentiation of adipocytes, demonstrating gene activation and signaling pathways, in relation to lipodystrophies: lipodystrophy genes and their associated protein products are shown in bold. Mesenchymal stem cells have the pluripotent ability to differentiate into osteocytes, myocytes, chondrocytes, stromal cells, or adipocytes. Wnt signal transduction pathways and other transcription factors lead to the development of a committed preadipocyte. Subsequently, adipogenic stimuli, such as insulin, glucocorticoids, IGF-1, and prostaglandins, initiate cell changes that lead to differentiation into an adipocyte. Current data suggest that the *BSCL-2* gene, coding for seipin, and the *AKT-2* gene play a role in adipocyte differentiation, and their mutations are involved in congenital generalized lipodystrophy (CGL) type 2 and familial partial lipodsytrophy (FPL) type 4, respectively. CCATT–enhancer-binding protein (C-EBP) β/δ transcription factors stimulate factors PPARγ, C-EBPα, and sterol regulatory element–binding protein (*SREBP*) 1c, which are upregulated in this process; PPARγ mutations are associated with FPL3, and intracellular lipid accumulation in an adipocyte is dependent on substrate availability. In response to a variety of lipogenic signals, the adipocyte matures as the size of the lipid droplets increases. Fatty acid synthase (*FAS*), acetyl coenzyme A carboxylase, and diacylglycerol acyltransferase (*DGAT*) expression are upregulated, which is necessary for the biosynthesis of phospholipids and triglycerides. *AGPAT2* is responsible for acylating phosphatidic acid to synthesize triglycerides and phospholipids, and its mutation is involved in CGL1. *PTRF* regulates caveolae intracellularly, and its functional loss results in CGL4. Apoptosis of adipocytes is influenced by *LMNA,* encoding for nuclear lamina proteins, and the *ZMPSTE24* gene product is required for posttranslational lamin A and C processing. Mutations in these genes lead to mandibuloacral dysplasia via premature nuclear disruption.

Congenital generalized muscular weakness and cervical spine instability have also been reported in occasional cases.[31] Many females have polycystic ovaries and may also present with enlarged clitoris, hirsutism, and absence of regular menstrual cycles or oligomenorrhea. Only a few affected women have had successful pregnancies, whereas affected men have normal fertility. Other rare manifestations of CGL include postpubertal focal lytic lesions in the long bones,[32-34] mild mental retardation,[28] and hypertrophic cardiomyopathy.[35-37] The basal metabolic rate may also be increased. Although patients may have accelerated linear growth and advanced bone age during their childhood, they normally have normal or reduced heights as adults.

Although both sexes are affected at similar rates, the multiple metabolic features associated with this syndrome tend to be more severe and develop earlier in girls. Children with CGL tend to have voracious appetites and accelerated growth; precocious menarche and/or pubarche, signaling early puberty, are rarely observed. Insulin resistance has been noted at an early age and may be present even at birth. Although diabetes is infrequently seen in infancy, its development is common during adolescence or young adulthood. It is rarely ketotic and is usually refractory to insulin therapy. Diabetic complications of nephropathy, retinopathy, acute pancreatitis, and hepatic steatosis are typically present and are a major cause of morbidity in affected individuals. Dyslipidemia poses a therapeutic dilemma as well. Hypertriglyceridemia is characterized by increased concentrations of very low-density lipoproteins and chylomicrons, whereas serum high-density lipoprotein (HDL) is usually low. Individuals with CGL may develop severe hypertriglyceridemia even from the first months of disease that may lead to acute pancreatitis.[38] Severely elevated triglycerides may not only provoke acute pancreatitis, but are also frequently related to the development of fatty liver disease. This commonly progresses to cirrhosis, which in many cases may be fatal. Serum adipocytokines, the hormones produced by adipose tissue (such as leptin and adiponectin), circulate in extremely low levels in CGL.[10] Patients with CGL usually demonstrate low leptin levels (~1.0 ng/mL), regardless of age or gender.[39] At least four molecularly distinct forms of congenital lipodystrophy have been defined, with mutations in *AGPAT2* and *BSCL2* responsible for 95% of reported cases of CGL.

Type 1 CGL (CGL1) is caused by *AGPAT2* gene mutation, as first described in 1999. This gene has been mapped to chromosome 9q34.[40,41] It encodes the enzyme 1-acylglycerol-3-phosphate O-acyltransferase 2 (AGPAT2), a lysophosphatidic acid acyltransferase isoform consisting of 278 amino acids localized within the endoplasmic reticulum (ER) membrane. It is highly expressed in white adipocytes[42] and catalyzes the acylation of lysophosphatidic acid to form phosphatidic acid, a key intermediate in the biosynthesis of triacylglyceride and glycerophospholipids.[43] AGPAT2 deficiency leads to a reduction of triglycerides inside the adipose organ and impaired signaling of critical elements engaged in adipogenesis such as PI3K/AKT and peroxisome proliferator-activated receptor gamma (PPARγ).[44] Only metabolically important adipose tissue (e.g., intraabdominal, intermuscular, subcutaneous, bone marrow) and not mechanically important adipose tissue (e.g., soles, palms, scalp, periarticular) are markedly reduced in patients with type 1 CGL. Forty-two mutations of the *AGPAT2* gene have been identified in 150 individuals, and the number of the related variants has increased over time.[45,46] Two more novel mutations of *AGPAT2* were recently observed in Italian individuals with CGL1.[46] Genetic testing of the first case revealed a point mutation (c.430C>T) in exon 3 of the *AGPAT2* gene. The patient, a 7-year-old boy, demonstrated clinical characteristics of CGL (namely lipoatrophy sparing the palms and soles, and muscle hypertrophy), as well as severe hypertriglyceridemia, elevated liver enzymes, and hepatic steatosis. The other case had a homozygous *AGPAT2* missense variant (c.475C>G, resulting in p. Arg159Cys) in exon 3. The 53-year-old female patient was diagnosed with lipoatrophic diabetes, bilateral proliferative retinopathy, diabetic and hypertensive nephropathy, hyperphagia, eruptive xanthomatosis, liver steatosis, and splenomegaly. The patient displayed signs of acromegaly (marked prognathism and enlarged hands and feet), muscle hypertrophy, phlebomegaly, acanthosis nigricans, and umbilical hernia.

Type 2 CGL (CGL2) is associated with *BSCL2* gene mutations including base substitutions, insertions, and deletions, events that can introduce a frameshift and/or a premature stop codon. This gene is located on chromosome 11q13 and encodes a 398–amino-acid protein named seipin, as a tribute to Martin Seip.[47] The *BSCL2* gene mutation has been found in patients of European and Middle Eastern origins, as well as those from South America and southern Asia. At least 36 genetic mutations of BSCL2 have been identified in 167 individuals.[45] Seipin is expressed diffusely in many tissues but predominantly in testis and brain[47]; its function in humans is largely unknown but includes adipocyte differentiation and lipid droplet formation.[48] According to a study performed in yeast, seipin is important for lipid droplet morphology and perhaps assembly.[26] Several studies indicate that *BSCL2* expression is critical for normal adipogenesis *in vitro*, as cells lacking *BSCL2* failed to induce expression of key lipogenic transcription factors (PPARγ and CCAAT/enhancer binding protein alpha [C/EBP-α]), as well as enzymes (AGPAT2, DGAT2, and lipin 1).[49-51] *BSCL2* mutations are usually related to a more predominant adipose tissue loss than in CGL1.[26] CGL attributed to *BSCL2* mutation appears to have a more severe disease phenotype than that owing to *AGPAT2* mutation, with a higher incidence of premature death and a lower prevalence of partial and/or delayed onset of lipodystrophy.[28] Furthermore, some patients with *BSCL2* mutations present with cardiomyopathy even from a young age[35] and have a higher prevalence of intellectual impairment.[27,28]

Compared with patients with CGL1, CGL2 patients have a more pronounced absence of adipose tissue. In addition to the loss of metabolically active fat (subcutaneous regions, intermuscular regions, bone marrow, intraabdominal and intrathoracic regions), CGL2 patients also lack mechanical fat (orbital regions, palms, soles, and joints).[23]

Both type 3 and type 4 are rarely observed and demonstrate some discrete clinical characteristics that are not present in type 1 or 2. Pathogenic variants of the caveolin 1 (*CAV1*) gene cause type 3 CGL, whereas variants in the polymerase I and transcript release factor (*PTRF*) gene are responsible for the development of type 4.[52,53]

Type 3 CGL (CGL3) is caused by *CAV1* gene mutations and was first described in 2008.[52] *CAV1* is located on chromosome 7q31, and its end product, caveolin 1, is a highly conserved 22-kD protein. The latter is a crucial component of plasma membrane microdomains known as *caveolae.* These domains have important roles in regulating signaling pathways and processes such as cell migration, polarization, and proliferation. Caveolae also promote insulin signaling and inhibit PKA signaling.[54] Caveolin 1 has been identified as a major binder of fatty acids on the plasma membranes, translocating them to lipid droplets. *CAV1* knockout mice are resistant to diet-induced obesity and exhibit severe hypertriglyceridemia, high postprandial free fatty acid (FFA) levels, reduced levels of both high and total molecular weight adiponectin, and increased risk of diabetes mellitus, atherosclerosis, and cardiovascular disease.[54-56] Mutated CAV1 may induce lipodystrophy by interfering with lipid handling, lipid droplet formation, and adipocyte differentiation[26,57] and is phenotypically classified as type CGL3. A mutation has been identified in one individual with CGL[24,52,58] who had a homozygous nonsense mutation of *CAV1,* probably as a result of a consanguineous union. The patient with *CAV1* mutation (CGL3) had clinical features similar to those of patients with CGL1 and CGL2, whereas the degree of her lipodystrophy was intermediate between these two phenotypes. The patient had also developed diabetes mellitus in adolescence and presented some distinctive features, including hypomagnesemia, hypocalcemia (probably owing to vitamin D resistance), functional megaoesophagus, short stature, and decreased bone density. The patient still preserved both mechanical adipose tissue and bone marrow fat, whereas the metabolically active adipose tissue was absent. Three distinct mutations of *CAV1* gene (one in exon 2 and two in exon 3) were identified in five individuals. Two of the three mutations were nonsense mutations (c.112G>T, p.Glu38 and c.424C>T, p.Gln142*), and the third was a frameshift mutation (c.479_480delTT, p.Phe160fs*).[45]

In 2009, Hayashi et al. reported for the first time a new type of CGL linked with mutations in the *PTRF*, gene, also known as *CAVIN1*.[53] Type 4 CGL (CGL4) is caused by homozygous or compound heterozygous mutations in the *PTRF* gene, which is located at 17q21.2, and its product Cavin-1 (PTRF) is involved in biogenesis of caveolae, regulating caveolin 1 and 3 expression.[53] It should be mentioned that caveolin 3 is most prevalent in muscle tissue, including cardiac myocytes.[59] It consists of 151 amino acids and is involved in signal transduction on the myocardial cell membrane and regulation of ion channel function in caveolae.[60]

Cavin-1 is a peripheral membrane protein localized on the inside surface of caveolae that supports the stabilization and assembly of the membrane structure, probably through interaction with the cellular cytoskeleton.[53,61] Cavin-1 is present in adipocytes and regulates their differentiation and the expandability of adipose tissue.[61,62] In type 4 CGL, adipose tissue loss may occur progressively during infancy and is significant in several areas of the body, including the face.

To date, 34 patients with 14 different mutations of the *CAVIN1* gene have been reported in the literature. Frameshift mutations were found to be most common, followed by nonsense and missense mutations.[45] Clinical features include generalized lipodystrophy in association with congenital distal myopathy, muscular hypertrophy, osteopenia, distal metaphyseal deformation, atlantoaxial instability, pyloric stenosis, gastrointestinal dysmotility, hepatosplenomegaly, and acromegaloid characteristics[31,53,63] Other findings are hypertriglyceridemia, insulin resistance, and elevated serum creatine kinase concentration. These patients exhibit a high risk of QT interval prolongation, cardiomyopathy, cardiac fibrosis, life-threatening cardiac arrhythmias such as exercise-induced ventricular tachycardia, catecholaminergic polymorphic ventricular arrhythmia, and sudden death.[59,63-66] One potential link between type 4 CGL and these serious cardiac complications is the impact of CAVIN1 on the expression pattern of caveolin-3 in cardiac myocytes.[60,67,68]

KEY POINTS

- Congenital generalized lipodystrophy (CGL) is a rare heterogeneous autosomal recessive syndrome observed mainly in cases of parental consanguinity. It is characterized by near-complete absence of body fat that may spare the supportive adipose tissue, as well as extreme muscularity, present at birth or soon thereafter. Patients with CGL develop profound hypoleptinaemia, and they are predisposed to metabolic disorders. Four distinct subtypes of congenital lipodystrophy have been defined, with *AGPAT2* and *BSCL2* mutations being the most frequent. Metreleptin is approved for use in patients with CGL.

EPIDEMIOLOGY: ETIOLOGY

Congenital generalized lipodystrophy (CGL) is a rare heterogeneous autosomal recessive syndrome observed mainly in cases of consanguinity and in isolated communities. Approximately 300 patients with CGL have been described. Four molecularly distinct subtypes of congenital lipodystrophy have been defined, with *AGPAT2* and *BSCL2* mutations being the most frequent.

PATHOPHYSIOLOGY

The pathophysiology of congenital generalized lipodystrophy may include impaired signaling of PI3K/AKT and PPARγ, affecting adipogenesis and lipid storage; defects in adipogenesis and expression of several enzymes (AGPAT2, DGAT2, and lipin 1) and lipogenic transcription factors (PPARγ, C/EBP-α); impaired lipid droplet biogenesis, accumulation, and metabolism; and defects in adipocyte differentiation, adipose tissue expandability, caveolae formation, and stability.

MAIN CLINICAL CHARACTERISTICS

Congenital generalized lipodystrophy (CGL) is characterized by near-complete absence of body fat that may spare the supportive adipose tissue, as well as extreme muscularity present at birth or soon thereafter. Patients with CGL develop profound hypoleptinaemia and are predisposed to metabolic disorders.

Other Mutations Associated With a Congenital Generalized Lipodystrophy–Like Phenotype

There are several patients with the CGL phenotype who do not have mutations in any of the four genes known to be mutated in CGL, which suggests that novel CGL-related genes have yet to be identified.

PPARγ plays an important role in adipogenesis and lipid synthesis. Mutations in the *PPARγ* gene are involved in the pathogenesis of FPL; however, biallelic *PPARγ* pathogenic variants may be associated with generalized lipodystrophy (recessive). A female patient has been reported with compound heterozygous mutations (c.413_416delAATG; p.Glu138Valfs*168 and c.490C>T; p.R164W) and a similar CGL phenotype. The individual showed the hallmark features of early onset of CGL with some facial adipose tissue. Moreover, the patient developed hypertriglyceridemia, eruptive xanthomata, acanthosis nigricans, insulin-resistant diabetes, end-stage renal disease, hyperparathyroidism, irregular menstruation, prominent veins, and marked hepatosplenomegaly. She has also experienced several episodes of pancreatitis and secondary bone fractures, and her plasma leptin levels are barely detectable.[69]

The *LMNA* gene encodes the nuclear envelope proteins lamin A and lamin C. Pathogenic variants of *LMNA* lead to the production of abnormal lamins and disrupt the interaction between chromatin and the nuclear lamina, which may result in apoptosis and premature adipocyte death. However, the pathogenic mechanisms by which these variants modify adipocyte function are still not fully understood.

Mutations in *LMNA* are associated with the development of FPL and progeroid syndrome.[70,71] However, a heterozygous lamin A/C (LMNA) p.T10I mutation was reported to be associated with near total loss of adipose tissue developing in early childhood, diabetes mellitus, insulin resistance, acanthosis nigricans, hypertriglyceridemia, hepatomegaly, and progeroid features.[72,73] Thus, it has been proposed that this should also be included as a potential CGL subtype.[73] Recently, a novel mutation in the *LMNA* gene and a subsequent autosomal recessive lipodystrophy syndrome was reported in two sisters aged 17 and 19 years old. Both individuals had the homozygous mutation p.Arg545his in *LMNA*, probably as a result of a consanguineous union. The patients had developed near-generalized loss of subcutaneous adipose, severe hypertriglyceridemia, hepatic steatosis, hepatomegaly, diabetes mellitus, short stature, intellectual disability, thin lips with perioral pigmentation, dry skin, bilateral clinodactyly of the toes, joint contractures, dystrophic nails, bilateral cataracts, and genitourinary disorders such as uterine fibroids, ovarian cysts, and hydrosalpinx.[74]

Another CGL-related gene variant involve mutation of the proto-oncogene encoding the cFOS protein. Sequence analyses performed in a White female patient with the typical appearance of CGL and insulin resistance identified a novel homozygous point mutation (c.–439, T>A) in the *C-FOS* promoter. No relevant mutations of the known pathogenic genes were identified. Her parents were healthy, not consanguineous, and did not carry this mutation. The patient died at the age of 8 years; the primary cause of death was hyper acute varicella infection. However, by the age of 5 years, the patient had also developed acanthosis nigricans, insulin resistance, prediabetes, severe hypercholesterolemia, mild hypertriglyceridemia, lipoatrophy and marked muscularity associated with complete loss of subcutaneous adipose tissue, hypertrichosis, and progressive hepatosplenomegaly. It has been proposed that diminished *C-FOS* expression potentially interferes with other genes essential for initiation of adipocyte differentiation or maturation of preadipocytes, and thus might play a role in CGL development.[75]

Acquired Generalized Lipodystrophy. The acquired syndrome of total lipoatrophy, also known as Lawrence syndrome, is similar to that of the congenital disorder, except that it develops in a previously healthy individual over days to weeks, often after a nonspecific febrile illness. The syndrome is very rare, has a later onset compared with CGL, and is more prevalent in females than males, with a ratio of 3:1. It commonly develops during childhood and adolescence, predominantly in White patients.[24,76]

In addition to the generalized loss of fat that has an active metabolic function, as seen in CGL, fat loss in AGL also occurs in palms, soles, and genital areas. In some cases, facial lipoatrophy is not initially present but develops gradually. However, retroorbital and bone marrow fat may be preserved.[58]

The median time to develop diabetes after loss of fat tissue is approximately 4 years.[58] Diabetic ketoacidosis has been reported, and severe hypertriglyceridemia, hepatic steatosis, acanthosis nigricans, menstrual irregularities, and polycystic ovary syndrome (PCOS) are also common findings.[58] Patients with AGL also have markedly reduced adiponectin levels and moderately reduced leptin levels.[10]

Several autoimmune diseases and inflammatory conditions have shown a temporal relationship with AGL. These include juvenile-onset dermatomyositis (JDM), rheumatoid arthritis, systemic sclerosis, systemic lupus erythematosus, Sjögren syndrome, and panniculitis.[58,77] JDM shows a particularly strong correlation with lipodystrophy; 8% to 40% of patients with JDM develop acquired lipodystrophy.[78-81] The chronicity and severity of JDM, as well as the high frequency of calcinosis, have been shown to predict the onset of lipodystrophy.[78] AGL following autoimmune diseases is also termed *AGL type 2* or the *autoimmune disease variety*. Patients with type 2 AGL tend to be older compared with patients with other AGL types.[58] Recently a new heterozygous missense mutation c.29C>T (p.T10I) in the *LMNA* gene was described in a 17-year-old African-American female patient with JDM and AGL. The patient had progressive subcutaneous adipose loss that started in the extremities and progressed to the entire body, including the face. Other characteristics include severe hypertriglyceridemia (>10,000 mg/dL), hepatosplenomegaly, nonalcoholic steatohepatitis, acute pancreatitis, diabetes, acute diabetic ketoacidosis, PCOS, ovarian cysts, bilateral renal cysts resulting in nephromegaly, micrognathia, bilateral parotid enlargement, atrial septal defect, and moderate aortic stenosis.[82]

Panniculitis is another inflammatory condition that frequently heralds the onset of AGL. It is estimated to be present in approximately 25% of affected patients.[58,83] Panniculitis manifests as subcutaneous inflammatory nodules that show a mixed infiltrate of lymphocytes and mononucleated macrophages in adipose tissue. The course of AGL is frequently protracted in patients with panniculitis and linked to less fat loss, lower prevalence of diabetes, and less severe metabolic disorders (e.g., mild hypertriglyceridemia).[76,79] The panniculitis variety is also known as *AGL type 1*. Up to 50% of AGL patients have no apparent history of autoimmune disease or panniculitis, however. These lipodystrophies are known as *AGL type 3* or the *idiopathic type*.

Of note, according to several recent studies, AGL is associated with antiprogrammed cell death 1 (anti-PD1) therapy and may result in severe metabolic complications. Evidence suggests that PLIN1 autoantibodies may be a possible cause of AGL development in these patients.[84] Anti-PD1 therapy is an advanced anticancer therapy with substantial and significant antitumor activity that targets several types of cancers. As a result, anti-PD1 has come to be used more frequently over time. Thus, physicians should be aware of this potential adverse event, as early recognition is of paramount importance.[85-87]

The pathogenesis of AGL is unknown. The autoimmune-mediated destruction of adipocytes or preadipocytes has been hypothesized to be the underlying mechanism. Autoantibodies against adipocyte membranes may also impair fat uptake and adipocyte differentiation.[77,78,88] Several antibodies have been found to be present in AGL, but no causative relationship has been established.[78] Cytokines, including tumor necrosis factor alpha (TNF-α) and interleukin 1 (IL-1), are also likely to play important roles in the immunopathogenesis of lipodystrophy. They can potentially lead to lipodystrophy by inhibiting adipogenesis[89] or increasing receptor-mediated apoptosis of adipocytes and preadipocytes.[90] Other studies in patients with AGL have documented an association between complement activation and adipocyte destruction.[91] Chronic hepatitis with autoimmune features and low serum complement 4 levels is also reported in some patients with AGL, suggesting involvement of the classical complement pathway causing loss of fat.[92] However, it is still not clear whether this association is characteristic of lipodystrophy or rather an outcome of the autoimmune process itself.

EPIDEMIOLOGY

Acquired generalized lipodystrophy is a rare syndrome (~80 patients) that develops in a previously healthy individual.

PATHOPHYSIOLOGY

The pathophysiology of acquired generalized lipodystrophy is not fully clarified, although several autoimmune diseases and inflammatory conditions have been shown to have a temporal relationship with this condition.

MAIN CLINICAL CHARACTERISTICS

Patients present with generalized loss of fat and marked metabolic disorders, including severe hypertriglyceridemia, nonalcoholic steatohepatitis, acute pancreatitis, acanthosis nigricans, diabetes mellitus, and polycystic ovary syndrome.

Partial Lipodystrophies

Partial lipodystrophy is characterized by selective regional fat loss. It is often associated with hypertrophy of adipose tissue in nonatrophic areas and is subclassified into inherited and acquired forms.

Familial Partial Lipodystrophies. Several syndromes have been described according to distinctive clinical features or underlying pathogenetic mechanisms. Most are inherited in an autosomal dominant fashion, and the patients are born with normal fat distribution but notice local fat loss, usually during puberty. FPLs exhibit phenotypic heterogeneity that has not yet been fully delineated.

Familial Partial Lipodystrophy Type 1 or Köbberling-Type Lipodystrophy. Also known as *Köbberling-type lipodystrophy,* FPL type 1 (FPL1) was first reported by Köbberling and colleagues in 1971. In comparison to other forms of FPL, the loss of adipose tissue is restricted to the extremities. The distribution of fat on the face and neck is normal or increased, frequently in association with significant central obesity. The hallmark anthropomorphic feature of this syndrome includes a palpable "ledge" formed between the normal and lipodystrophic areas and high triceps-to-forearm and abdomen-to-thigh skinfold ratios.[93] Metabolic syndrome, especially hypertriglyceridemia, is common in FPL1. This correlates with a high incidence of pancreatitis and premature coronary artery disease. Leptin concentrations are low and correspond to the body mass index (BMI) and the level of fat loss of individual patients.[93]

Mostly women have been diagnosed with FPL1 to date, as they are more severely affected than men. Diagnosis of affected men is difficult given the normal muscular physique and very mild clinical presentation that does not allow early detection. FPL1 tends to have a childhood onset, with metabolic complications occurring during adulthood. Acanthosis nigricans is present on the neck, axillae, and groin but is usually mild.

The genetic defect associated with FPL1 is currently unknown, and no *LMNA* or *PPARγ* mutations have been identified. It appears that this syndrome may be familial for some patients but may also occur spontaneously. However, according to recent studies, a significant number of cases of FPL1 follow polygenic inheritance.[93-95]

Familial Partial Lipodystrophy Type 2 or Dunnigan-Variety (Face-Sparing) Lipodystrophy. Also known as *Dunnigan variety (face-sparing) lipodystrophy,* FPL type 2 (FPL2) is an autosomal dominant condition found mostly, but not exclusively, in subjects of northern European descent. More than 300 cases have been reported, but the true prevalence of this syndrome is thought to be much higher. Currently known cases are associated with variants in exon 8 of the *LMNA* gene.[11] It is characterized by gradual loss of almost all subcutaneous fat from the extremities, commencing at puberty. This gives rise to the characteristic phenotype of "increased muscularity" in the arms and legs. Variable and progressive loss of fat from the anterior abdomen and chest occurs later. Excess fat may subsequently accumulate in the face and neck and in the intraabdominal region, resulting in a Cushingoid appearance.[24]

Affected females tend to have more recognizable phenotypes. Although questions of gender differences have been raised, anthropometric measures and MRI data demonstrated that both affected men and women have similar patterns of fat loss. In comparison to the affected men, women may have more severe hypoleptinemia and metabolic sequelae (insulin resistance), and they may also have higher prevalence of diabetes and atherosclerotic vascular disease, as well as higher serum triglycerides and lower high-density lipoproteins. The prevalence of hypertension and fasting serum insulin concentrations are similar in men and women.[58,83] The prevalence of diabetes is not related to age, menopausal status, or family history of type 2 diabetes.[88]

Patients with FPL2 are more prone to develop PCOS, infertility, and gestational diabetes. The prevalence of gestational diabetes and miscarriage is significantly higher in these patients than in women with similar BMI and PCOS.[96]

The first gene identified as containing mutations associated with FPL2, named *LMNA,* is located on chromosome 1q21-22. As previously mentioned, *LMNA* encodes lamins A and C, which are essential components of the nuclear lamina and provide structural integrity for the nuclear envelope. Most FPL2-associated mutations in *LMNA* are missense mutations within the 3′ end of the gene,[97] whereas the *LMNA* mutations leading to the R482W and R482Q amino acid substitutions seem to be the most common pathogenic variants.[98,99] The mutant gene products may disrupt interaction with chromatin or other nuclear lamina proteins, resulting in apoptosis and premature death of adipocytes.[100] The accumulation of prelamin A may also impair adipogenesis by interfering with the key adipocyte transcription factors/regulators, including sterol response element-binding protein 1 (SREBP-1) and PPARγ.[100-103] It is interesting to note that there is no difference in the levels of lamin A and lamin C expression in different adipose depots, even though the fat loss associated with FPL2 is regionally selective, suggesting that the downstream effects of *LMNA* mutations are differentially regulated in different areas of the body.[96]

According to recent findings, there is an anthropometric, clinical, and biochemical phenotypic heterogeneity among individuals with FPL2 based on *LMNA* mutation site and gender.[104] Females tend to have a more severe FPL2 phenotype, likely because of increased levels of proinflammatory cytokines or glucocorticoid receptor GRβ overexpression and *LMNA* mutations affecting both lamins A and C.[104] It has also been suggested that the percentage of fat in the lower limb is the most reliable anthropometric measure for FPL2 diagnosis in women. Females with coexisting metabolic disorders and a negligible lower limb fat content (<1st percentile) should undergo genetic testing for FPL2.[105]

Familial Partial Lipodystrophy Caused by PPARγ Mutations, or Familial Partial Lipodystrophy 3. Also referred to as FPL3, FPL caused by *PPARγ* mutations is associated with heterozygous mutations of the *PPARγ* gene on chromosome 3p25.[106] The phenotype is similar to that of FPL2, with the exception that fat accumulation in the head and neck may not occur.[106-109] Patients with FPL3 appear to have more severe metabolic abnormalities than those with FPL2.[103]

PPARγ encodes the peroxisome proliferator–activator receptor, which belongs to the superfamily of nuclear hormone receptors. It is expressed at high levels in adipocytes and plays an essential role in adipocyte differentiation and adipogenesis.[110] Heterozygous mutations may cause loss of function by directly interfering with normal gene function (dominant negative) or by reducing gene expression (haploinsufficiency).

Recently it was found that a novel missense heterozygous mutation,(c.1060A>G; p.Ile354Val) in *PPARγ2* is responsible for a decrease (i.e., ~ 30%–35%) in receptor transcriptional activity and for the development of FPL3 in an Italian family. This finding suggests that *PPARγ* mutations that affect transcriptional activity to a lesser extent than haploinsufficiency may be also responsible for FPL3 development.[111]

Familial Partial Lipodystrophy Caused by PLIN1 Mutation, or Familial Partial Lipodystrophy 4. Also known as *FPL4,* FPL caused by *PLIN1* mutation has been characterized phenotypically as loss of subcutaneous fat from the extremities. FPL4 is associated with mutation in the *PLIN1* gene coding for perilipin 1, which is a required component of lipid droplet membranes and is essential for lipolysis and lipid storage. Six patients with this mutation had histologically small adipocytes with increased macrophage infiltration and abundant fibrosis.[112] Recently, renal involvement has been described for the first time as a clinical manifestation in a patient with FPL4. In more detail, a novel heterozygous frameshift mutation (c.1201_1202insT) was described in a 15-year-old Chinese female with insulin-resistant diabetes, hypertriglyceridemia, nonalcoholic steatohepatitis, and proteinuria. [113]

Familial Partial Lipodystrophy Caused by CIDEC Mutation, or Familial Partial Lipodystrophy 5. FPL5 is a rare autosomal recessive condition that appears in early childhood and it is caused by pathogenic variants in the *CIDEC* gene. The *CIDEC* gene is located on chromosome 3 (3p25.3) and participates in adipocyte differentiation.

It also encodes the CIDEC protein, which is an essential regulator of glucose and lipid metabolism and insulin sensitivity. Pathogenic variants of *CIDEC* are hypothesized to prevent lipid droplets from storing fat and cause defects in adipocyte differentiation.[114,115] FPL5 is characterized by partial lipodystrophy and muscular hypertrophy, but no accumulation of adipose tissue, acanthosis nigricans, metabolic abnormalities, severe insulin-resistant diabetes, and hepatic steatosis. Recently, two single nucleotide polymorphisms (rs2479 or C allele at rs1053239) were associated with abnormal fasting glucose levels and hypertriglyceridemia. Patients with an A allele at rs2479 or a C allele at rs1053239 tend to rapidly develop high blood pressure and benefit from angiotensin II–targeted treatment.[116]

Familial Partial Lipodystrophy Caused by LIPE Mutation, or Familial Partial Lipodystrophy 6. FPL6 is an autosomal recessive syndrome, and only a few cases have been reported to date. It appears in adulthood and is caused by mutations in the *LIPE* gene (lipase E, hormone-sensitive type). It is associated with impaired lipolysis, which may result simultaneously in lipomatosis and partial adipose loss. It is also characterized by insulin resistance, diabetes, hypertriglyceridemia, and hepatic steatosis.[117] Individuals with FPL6 may exhibit multiple symmetric lipomatosis, accumulation of adipose tissue in the neck, axillae, supraclavicular area, and back, partial adipose tissue loss from the lower extremities, and in some cases distal symmetric muscular dystrophy.[117,118]

Familial Partial Lipodystrophy Caused by AKT2 Mutation. FPL caused by *AKT2* mutation has been reported in a single family by George and associates.[119] It is inherited in an autosomal dominant fashion and manifests as severe insulin resistance and partial lipodystrophy confined to the extremities.[119] Although the specific mutations in *AKT2* has not yet been identified, and this conditions is not included in earlier FPL classification systems,[98] recent studies consider it to be another FPL syndrome.[2,73]

AKT, also known as protein kinase B, is a serine/threonine protein kinase and plays multiple roles in cell signaling, cell growth, and glycogen synthesis, as well as in insulin-stimulated glucose transport.[120] Lipodystrophy in patients with *AKT2* mutations is thought to be attributed to reduced adipocyte differentiation and dysfunctional postreceptor insulin signaling.

Familial Partial Lipodystrophy Caused by CAV1 Mutation. Heterozygous *CAV1* mutation has also been identified as a rare cause of partial lipodystrophy.[121] Two cases with different frameshift *CAV1* mutations have been reported. Both patients were described to have partial lipodystrophy with subcutaneous fat loss in the face and upper body, micrognathia, and congenital cataracts. One case also exhibited abnormal neurologic findings. Diabetes, hypertriglyceridemia, and recurrent pancreatitis were reported in both cases.[121]

Familial Partial Lipodystrophy Caused by PCYT1A Mutation. Another gene that has been reported to be associated with FPL is the phosphate cytidylyltransferase 1 alpha (*PCYT1A*) gene. PCYT1A is the rate-limiting enzyme in the Kennedy pathway, participating in *de novo* phosphatidylcholine synthesis. Biallelic pathogenic loss-of-function mutations in *PCYT1A* have been reported to be associated with a severe form of partial lipodystrophy, significant insulin resistance and diabetes, severe nonalcoholic fatty liver disease, and low HDL cholesterol levels in two unrelated female patients.[122] Because of the phenotypes and characteristics of these patients, it has been suggested that this mutation could be considered a potential cause of CGL.[73]

Mandibuloacral Dysplasia–Associated Lipodystrophy. Mandibuloacral dysplasia (MAD) is an extremely rare autosomal recessive progeroid syndrome that has been reported in approximately 40 cases. MAD is characterized by postnatal growth retardation, craniofacial and skeletal abnormalities (mandibular and clavicular hypoplasia, delayed closure of the cranial sutures, acroosteolysis, joint contractures, birdlike face, dental abnormalities), cutaneous changes (restrictive dermatopathy, skin atrophy, alopecia, and mottled cutaneous pigmentation), and lipodystrophy. Although MAD is present at birth, dysmorphic manifestations and progeroid features become more prominent with time, and the full clinical phenotype is recognizable during the early school years. The patients have normal intelligence,[123] and their serum leptin concentration can be low or normal. Hyperinsulinemia, insulin resistance, impaired glucose tolerance, diabetes mellitus, and hyperlipidemia have been reported in some patients.

There are two distinctive phenotypes of MAD: type A involves the loss of subcutaneous fat from the extremities and trunk but normal or excessive deposition of fat in the face and neck, and type B is characterized by more generalized loss of subcutaneous fat and premature renal failure. MAD type A (MADA) is also considered to be as a result of mutations of the *LMNA* gene that result in accumulation of prelamin A and lead to alterations of nuclear architecture and chromatin defects. It remains unclear how different mutations in the same gene lead to a variety of phenotypes. Patients with MAD type B (MADB) have been reported to carry compound heterozygous mutations in *ZMPSTE24*, the gene encoding an endoprotease, zinc metalloprotease, which is located on chromosome 1q34. The enzyme is important in posttranslational processing of prelamin A to mature lamin A. Recently, eight related Surinamese individuals of African descent with MADB were described. All of these individuals, however, shared the same homozygous founder mutation in the *ZMPSTE24* gene, resulting in a missense variant c.1196A>G, p.(Tyr399Cys).[124] As in MADA, the accumulation of farnesylated prelamin A is proposed to be responsible for the phenotype.[123] Only eight other patients with *ZMPSTE24* mutations are known, the majority from Italy.[125] Focal segmental glomerulosclerosis and calcified skin nodules have been reported in patients with ZMPSTE24 deficiency.[126]

EPIDEMIOLOGY: ETIOLOGY

The majority of familial partial lipodystrophy (FPL) syndromes are inherited in an autosomal dominant pattern and are characterized by selective regional fat loss. More than 500 patients with FPL have been reported. Six main FPL types have been described that are caused by mutations in *LMNA*, *PPARγ*, *PLIN1*, *CIDEC,* and *LIPE*.

PATHOPHYSIOLOGY

The different types of familial partial lipodystrophy syndrome exhibit phenotypic heterogeneity and distinct genetic causes. The underlying pathophysiological mechanisms are not fully delineated and may involve disrupted adipogenesis, impaired differentiation of adipocytes, defects in lipid storage and lipolysis, increased adipocyte apoptosis, and premature adipocyte death.

MAIN CLINICAL CHARACTERISTICS

Patients are born with normal fat distribution, with the local fat loss occurring later in life, usually during puberty. Muscular hypertrophy and cardiometabolic disorders are common.

Autoinflammatory Syndromes. Several autoinflammatory syndromes may also be associated with lipodystrophic states. A rare autosomal recessive, autoinflammatory syndrome presenting with joint contractures, microcytic anemia, muscle atrophy, and panniculitis-induced lipodystrophy (JMP) in childhood has recently been reported in three individual patients from Japan and two families from Mexico and Portugal.[127] Additional clinical features of JMP include hepatosplenomegaly, intermittent fever, calcification of the basal ganglia, and hypergammaglobulinemia. Sequencing of candidate genes involved in immune system dysfunction led to the discovery of a loss-of-function mutation of the proteasome subunit beta-type 8 (*PSMB*-8) gene on chromosome 6. *PSMB8* encodes b5i, a catalytic subunit of immunoproteasomes, which mediates proteolysis and generates MHC class 1 molecules. Mutations may result in adipose tissue lymphocytic infiltration and loss of surrounding fat tissue.

CANDLE (chronic atypical neutrophilic dermatosis with lipodystrophy and elevated temperature) is another newly described syndrome causing partial lipodystrophy that has so far been reported in six patients and is likely inherited in an autosomal recessive fashion.[128,129] Infants present with annular violaceous plaques and recurrent fevers, with eventual loss of adipose tissue from the upper limbs and face.[130] Other associated clinical characteristics include hepatosplenomegaly, anemia, eyelid swelling, and calcifications of the basal ganglia. The molecular mechanism of this syndrome is yet to be determined. It has been proposed that physicians should include this syndrome in their differential diagnosis when treating individuals with early-onset systemic inflammatory disease and skin manifestations.[131]

Other Syndromes and Progeroid Disorders With a Component of Lipodystrophy. Multiple other syndromes are also linked to lipodystrophy, and several have been identified as laminopathies, including Hutchinson–Gilford progeria syndrome (a very rare and uniformly fatal segmental progeroid syndrome with progressive and generalized fat loss), restrictive dermopathy, progeria-associated arthropathy, and atypical progeroid syndrome.[15] The majority of these syndromes are associated with *de novo LMNA* mutations, yielding a MADA-type lipodystrophy.

Werner syndrome (short stature, birdlike appearance of the face, early onset of aging processes, and progeroid features) has been linked to homozygous mutations in *RECQL2,* which encodes a DNA helicase. In contrast, the genetic basis and inheritance patterns have yet to be clarified for the following syndromes: Cockayne syndrome (short stature, photosensitivity, hearing loss, premature aging, and progeroid appearance), carbohydrate-deficient glycoprotein syndrome (nonprogressive ataxia associated with cerebellar hypoplasia, stable mental retardation, variable peripheral neuropathy, and strabismus), SHORT syndrome (S–short stature; H–hyperextensibility of joints and/or hernia (inguinal); O–ocular depression; R–Rieger anomaly; T–teething delay), and ectodermal dysplasia in association with generalized lipodystrophy acral renal ectodermal dysplasia lipoatrophic diabetes (AREDYLD) syndrome.

Acquired Partial Lipodystrophy (Barraquer–Simons Syndrome). First reported in 1885 by Mitchell, acquired partial lipodystrophy (APL) was further characterized by Barraquer Roviralta in 1907. There have been approximately 250 cases reported in the English-language literature.[24]

Patients with APL are primarily of European descent; however, cases have also been reported in Asian Indian, Vietnamese, and Samoan populations. The disease shows a female dominance, with a 4:1 ratio, and most patients have clinical manifestations in early puberty or early adulthood, usually before 15 years of age. Female patients normally have regular menses and intact fertility. The characteristic fat loss progresses in a “cephalocaudal” fashion, with fat loss appearing first in the face and spreading to the upper part of the body. Fat under the umbilicus is rarely affected. Many patients develop excess fat accumulation over the lower abdomen, gluteal region, thighs, and calves. Breasts may lose fat and consist of firm glandular tissue only.[58]

In contrast to other types of lipodystrophies, acanthosis nigricans, hirsutism, and hypertrichosis are rare. Insulin resistance is uncommon, and the prevalence of diabetes is much reduced compared to other types of lipodystrophies. The prevalence of the metabolic syndrome is also significantly lower in patients with APL. Hepatomegaly is common among patients with APL. In the series of case reports by Misra and Garg, 35% of APL patients had hypertriglyceridemia, and a third had low concentrations of HDL.[58] Serum leptin levels were normal in the majority of patients.[10]

A strong association between APL and membranoproliferative glomerulonephritis (MPGN) type 2 has been proposed. The spectrum of presentation ranges from acute glomerulonephritis, hematuria, nocturia, urinary casts, albuminuria, and nephritic syndrome to chronic glomerulonephritis and uremia.[121,132] The serum C3 complement levels are usually low, with the presence of C3 nephritic factor,[121] which blocks degradation of the enzyme C3 convertase. Patients with low C3 levels tend to have an earlier onset of lipodystrophy than those with normal serum C3 levels. The median time interval between the onset of lipodystrophy and the development of MPGN is approximately 5 to 10 years but could be as long as 20 years.[121,133]

Similar to AGL, APL is also frequently seen in the context of autoimmunity or infections.[77] The most frequently cited infection preceding APL is measles. The low C3 levels may also render APL patients susceptible to recurrent pyogenic infections, particularly *Neisseria.*[134] Systemic lupus erythematosus and dermatomyositis/polymyositis are the autoimmune diseases that are most frequently associated with APL.[58] The precise mechanisms leading to adipose-tissue atrophy in APL remain unclear. C3 nephritic factor has been shown to induce lysis of adipocytes expressing factor D (adipsin).[58]

According to recent findings, C3 hypocomplementemia (and to a lower extent low serum C4 complement levels) and autoimmunity are associated with Barraquer–Simons syndrome (BSS). Furthermore, C3NeF, as well as other autoantibodies (such as anti-C3, anti-P, and anti-FB) against components of the C3 convertase of the alternative pathway, may also be present in several patients with BSS.[135]

Rare variants in the *LMNB2* gene encoding lamin B were reported in five APL patients, but half of those variants were also reported in normal controls.[136] In a study by Guallar and coworkers, *PPARγ* gene downregulation and mitochondrial toxicity were observed in a patient with APL, suggesting that impaired adipogenesis and adipocyte metabolism may also underlie the pathogenesis of APL.[137]

KEY POINTS

- Acquired partial lipodystrophy (APL) is more frequent in females, and most patients have clinical manifestations in early puberty or early adulthood. The etiology of APL is still uncertain, although an association with autoimmune-mediated loss of adipose tissue has been suggested. Patients with APL may demonstrate circulating autoantibody (C3 nephritic factor) and low complement component 3 levels. The progressive loss of adipose tissue follows a “cephalocaudal” trend, starting from the face and spreading to the upper part of the body, while fat may be preserved or accumulated over the lower abdomen, gluteal region, thighs, and calves. Membranoproliferative glomerulonephritis or autoimmune disease may exist. Associated metabolic syndrome, insulin resistance, and related complications are not common.

EPIDEMIOLOGY

Acquired partial lipodystrophy is more common in females than in males; approximately 250 patients have been reported.

ETIOLOGY: PATHOPHYSIOLOGY

Although the etiology of acquired partial lipodystrophy (APL) is still uncertain, a mechanism involving autoimmune-mediated loss of adipose tissue has been suggested. Patients with APL may demonstrate circulating autoantibody (C3 nephritic factor) and low complement component 3 levels.

MAIN CLINICAL CHARACTERISTICS

Most patients have clinical manifestations in early puberty or early adulthood.

The progressive loss of adipose tissue follows a "cephalocaudal" trend, starting from the face and spreading to the upper part of the body, while fat may be preserved or accumulated over the lower abdomen, gluteal region, thighs, and calves. Membranoproliferative glomerulonephritis or autoimmune disease may exist. There is a low prevalence of metabolic syndrome, insulin resistance, and related complications.

Human Immunodeficiency Virus–Associated Lipodystrophy Syndrome. Human immunodeficiency virus (HIV)-associated lipodystrophy syndrome (HALS) is currently the most common form of partial lipodystrophy. First reported in 1998, HALS mainly develops in patients infected with HIV who are receiving highly active antiretroviral therapy (HAART). Importantly, it is independent of fat loss caused by either the HIV infection itself or by cancers or opportunistic infections. The pattern of fat loss is also different. HALS patients may experience lipoatrophy, lipohypertrophy, or a combination of both, namely mixed lipodystrophy.[138,139] Cases of lipodystrophy have also been reported in HAART-naïve patients. The prevalence of HALS increases with increased duration of exposure to HAART and is reported to be present in up to 50% of patients on antiviral treatment for more than 1 year, thus affecting more than 100,000 patients in the United States.

HALS usually manifests as peripheral fat wasting that involves the face, arms, legs, and buttocks. The generalized depletion of subcutaneous fat in HALS is distinct from HIV-related wasting, which is associated with advanced acquired immunodeficiency syndrome and loss of other tissues, such as muscle mass. Accumulation of fat is frequently seen in the dorsocervical area ("buffalo-hump" pads), abdomen, occasionally in the breasts of both men and women, in the suprapubic area, under the axillae, and over the anterior aspect of the neck. Lipomatosis manifests in a small percentage of patients. Facial fat loss can be quite severe, sometimes resulting in an emaciated appearance. Most studies have shown an increase in central fat over the first 6 months after the initiation of antiretroviral therapy that subsequently levels off.

Most HIV-infected patients with lipodystrophy are otherwise relatively healthy, but dyslipidemia, especially hypertriglyceridemia, is common among HIV-infected patients receiving HAART. HIV viremia has been linked to decreased plasma concentrations of total, low-density lipoprotein (LDL), and HDL cholesterol, and at later stages elevated triglyceride levels. HAART has been shown to cause a worsening lipid profile, with increased plasma triglycerides, increased total and LDL cholesterol, and decreased HDL cholesterol, which can be further accompanied by increases in small, dense LDL particles, lipoprotein (a), and apolipoproteins B, C-III, E, and H.[140] HAART-associated dyslipidemia is associated with accelerated atherosclerosis and signs of endothelial dysfunction.[141-144] Seen in 35% of patients, insulin resistance and frank diabetes mellitus are more prevalent in HIV subjects with lipodystrophy,[145] but acanthosis nigricans seems to be extremely rare. These metabolic disorders are predictive of the development of metabolic syndrome, whereas their prevalence may vary among HIV-infected individuals, according to findings from different studies.[146,147] The underlying mechanisms related to the development of the metabolic syndrome and the different subtypes of lipodystrophy in HIV-infected population have not been fully elucidated, and seem to involve a multifactorial process.[148] The pathophysiology of metabolic syndrome in HIV patients may include HIV *per se*, duration of antiretroviral drug use, and chronic inflammation.[149] Moreover, findings suggest that variants in candidate genes associated with lipid metabolism and adipogenesis may be predictors of these metabolic and anthropometric disorders.[150,151]

Hepatic steatosis may also develop. Both leptin and adiponectin levels are decreased in patients with HALS. The reduction of leptin levels correlates with decreased subcutaneous fat mass,[152] whereas decreased adiponectin levels are more closely associated with intraabdominal fat accumulation.[153]

Fat atrophy and fat deposition appear to be associated with different risk factors in HALS. Low baseline fat mass and increased disease severity are associated with a higher incidence of fat atrophy.[154] Epidemiology studies have also shown that coinfection with hepatitis C virus can increase the chance of fat atrophy in HIV-infected individuals.[155] On the other hand, older age, female sex, high baseline body fat, increased HIV viral load, low CD4 count, and longer duration of HAART are associated with a higher risk for fat accumulation in HIV patients.[156,157]

The frequency and manifestations of lipodystrophy also differ with respect to the drugs used. Nucleoside reverse transcriptase inhibitors (NRTIs), particularly zidovudine and stavudine, are commonly associated with morphologic changes, particularly fat loss from the extremities, whereas protease inhibitors (PIs) are more frequently linked to hypertriglyceridemia, insulin resistance, and localized fat accumulation.[158] Interestingly, fat loss worsens with ongoing HAART therapy but does not reverse on its discontinuation. Because PIs and NRTIs are usually given in combination as part of HAART, the individual effects of each drug on phenotype are not clear.

The mechanism behind HALS is complex and is currently not completely understood.[159] HAART has been widely accepted as playing a central role in the development of lipodystrophy, but accumulating evidence indicates that the HIV virus *per se*, as well as host immune responses, also contribute to the development of HALS. NRTIs have been shown to suppress adipogenesis either through mitochondrial toxicity (by inhibiting mitochondrial DNA polymerase gamma) or by induction of genes that inhibit adipogenesis. *In vitro* studies suggest that zalcitabine, didanosine, and stavudine have the strongest effects in a reducing order of magnitude, whereas tenofovir and lamivudine show minimal or no mitochondrial toxicity.[138] Combinations of drugs can act synergistically and lead to mitochondrial depletion. In addition, zidovudine, emtricitabine, and abacavir can also impair cell proliferation and increase lactate and lipid production. NRTIs may also contribute to insulin resistance by altering the levels of IL-6, TNF-α, and adiponectin.[158]

PIs can lead to adipose tissue changes through several potential mechanisms: (1) impairment of adipocyte differentiation by downregulation of the expression of master adipogenic transcription factors, such as C/EBP-α and C/EBP-β, PPARγ, and SREBP-1;[13] (2) increase of adipocyte apoptosis, leading to a reduction in cell numbers; and (3) decrease of lipid accumulation in adipocytes through reactive oxygen species (ROS) production and increased macrophage recruitment.[160] Therapy with PIs has also been implicated in the causation of metabolic abnormalities by inhibiting glucose transport 4 (GLUT4)-mediated glucose transport; by suppressing insulin signaling; and through activation of lipolysis, induction of IL-6 and TNF-α, reduction in gene expression, and secretion of adiponectin, as well as proteasome dysfunction. According to a study, ritonavir significantly affected the expression of 389 genes involved in adipocyte differentiation, glucose metabolism, adiponectin secretion, and triglyceride accumulation. In detail, genes responsible for adipocyte triglyceride accumulation (namely *CFD*, *CIDEC*, and *PPARγ*) and glucose transport genes (including *GLUT4* and *ADIPOQ*) were downregulated. Moreover, the expression of PPARγ regulatory genes *CEBPA* and liver-X-receptor α was also reduced, whereas IL-6 was increased.[161] Lopinavir, ritonavir, saquinavir, and nelfinavir are the worst offenders. The newer PI, atazanavir, has a much milder effect. Indinavir does not have much effect on cell viability or lipogenesis but inhibits glucose uptake to a greater extent than the other PIs.[158]

Nonnucleoside reverse transcriptase inhibitors (NNRTIs), including efavirenz and nevirapine, appear to have more favorable safety profiles in terms of lipodystrophy complications. Although an *in vitro* study showed that efavirenz may interfere with adipogenesis by reducing the expression of SREBP-1, a key adipogenic transcription factor,[162] and a prospective randomized trial suggested that efavirenz could have greater potential for causing lipoatrophy than the combination of lopinavir plus ritonavir,[163] the results from several clinical studies imply that the potential role of efavirenz in the development of lipodystrophy is minimal, and that it may depend on the NRTIs that form the backbone of the regimen.[164] Lipoatrophy is lowest with the NRTI-sparing regimen of lopinavir and efavirenz, but this combination led to worsening dyslipidemia.[165] Additionally, *in vitro* data have shown that efavirenz may increase production of ROS, reduce lipid content in mature adipocytes, and inhibit mitochondrial activity.[162,166]

There is also increasing evidence that HIV-1 infection itself, regardless of HAART, may induce inflammatory and proapoptotic pathways in adipose tissue and thus contribute to lipoatrophy. *In vitro* experiments have demonstrated that the HIV-1 viral protein R may act as a corepressor of PPARγ-mediated gene transcription, inhibiting adipocyte differentiation.[167] This could be either occurring through the direct HIV-1 infection of cells in adipose tissue or may be mediated by HIV-1–encoded proteins.[168] Genetic background may also influence the degree of HALS. A single nucleotide polymorphism in the resistin gene has been associated with increased risk for developing limb fat loss, dyslipidemia, and insulin resistance in patients on HAART therapy.[169] Additionally, two single nucleotide polymorphisms in the adiponectin receptor gene *ADIPOR2* (rs11061925 and rs929434) have been found to be associated with biochemical parameters, such as the levels of triglycerides, total cholesterol, glucose and adiponectin, in HIV-infected men receiving HAART.[170]

Inflammatory cytokines, including interferon alpha (IFN-α), TNF-α, IFN-γ, monocyte chemoattractant protein-1 (MCP-1), IL-1, IL-6, and IL-12, may also contribute to or mediate the clinical manifestations of this syndrome,[152,168] and this remains an active area of research.

EPIDEMIOLOGY: ETIOLOGY

Human immunodeficiency virus (HIV)-associated lipodystrophy syndrome (HALS) is currently the most common form of partial lipodystrophy and develops in patients infected with HIV who are receiving highly active antiretroviral therapy. Approximately 40% of HIV patients receiving protease inhibitor therapy for more than 1 year develop HALS.

PATHOPHYSIOLOGY

The pathophysiological mechanism behind human immunodeficiency virus–associated lipodystrophy syndrome is complex and not fully elucidated. It may involve impaired adipogenesis and expression of adipogenic transcription factors (such as PPARγ, SREBP-1, C/EBP-α, and C/EBP-β), as well as defects in adipocyte differentiation and apoptosis.

MAIN CLINICAL CHARACTERISTICS

Patients may experience lipoatrophy, lipohypertrophy, or a combination of both, namely mixed lipodystrophy. Human immunodeficiency virus–associated lipodystrophy usually manifests as peripheral fat wasting involving the face, arms, legs, and buttocks, and excess fat deposition in the neck ("buffalo-hump" pads) and abdomen. Of note, nucleoside reverse transcriptase inhibitors are commonly associated with morphologic changes, particularly fat loss from the extremities, whereas protease inhibitors are more frequently linked to hypertriglyceridemia, insulin resistance, and localized fat accumulation. Patients may experience metabolic disorders, such as severe insulin resistance, diabetes mellitus, dyslipidemia, and liver steatosis.

Localized Lipodystrophies

Localized lipodystrophies are characterized by loss of subcutaneous adipose tissue from small areas or from small parts of an extremity, but insulin resistance or metabolic abnormalities do not usually develop in these patients. Drug-induced lipoatrophy at the site of insulin injection was a frequent complication before the availability of purified human insulin but is rather uncommon today. Localized hypertrophy is still frequently seen in patients who use the same injection site too often. Other rare causes of localized lipodystrophy as a result of repeated pressure in specific areas, to panniculitis, or as part of a rare syndrome called *lipodystrophia centrifugalis abdominalis infantilis* have been reported.[171]

MECHANISMS RESPONSIBLE FOR SEVERE INSULIN RESISTANCE

As mentioned earlier, the mechanisms of insulin resistance in several syndromes associated with lipodystrophy are not fully understood, and it is likely that the etiology of lipodystrophies is multifactorial. Lipodystrophy may develop because of abnormal preadipocyte development, adipocyte dysfunction, or increased fat cell death. The study of lipodystrophy syndromes provides unique insights regarding the lack of adipocyte enlargement and adipose expansion and the inability of subcutaneous fat to store excess energy. The excess energy is deposited as ectopic fat with a subsequent decrease in adipokine levels, mechanisms that are associated with the development and severity of insulin resistance.[4,16,172]

Inflammation is thought to contribute to insulin resistance via impairment of lipolysis and adipocyte metabolism.[173] TNF-α reduces insulin receptor kinase activity, downregulating insulin receptor substrate (IRS)-1 and GLUT-4 phosphorylation. Furthermore, IL-6 at elevated levels may induce triglyceride secretion from the liver and promote hepatic gluconeogenesis. The impaired secretion of adipokines, such as adiponectin and leptin, leads to abnormalities of insulin sensitivity. Finally, mitochondrial stress plays a key role in metabolic dysregulation. These mechanisms are further discussed in the following sections.

Fat Redistribution and Fat Metabolism

Changes in fat distribution (reduced subcutaneous fat with or without increased visceral fat) may cause increased insulin resistance. The lack of adipose tissue can result in inadequate storage of and therefore increased levels of FFAs. Intracellular fatty acid accumulation can directly inhibit insulin-mediated glucose transport in skeletal muscle,[174,175] and excess FFAs can also lead to lipotoxicity by inducing ectopic fat accumulation in the liver and muscle, where the adipose tissue is considered to have more "pathogenic" potential. The deposition of fat in the pancreas can also impair the β cell response and further contribute to insulin resistance.[176] Moreover, because the fat tissue at different depots shows different degrees of metabolic activity, such as lipolysis and inflammation, lipodystrophic states that are associated with higher volume of visceral fat and abdominal fat are likely to display a higher degree of insulin resistance.[176]

Adipocytokines

Alterations of adipocytokine levels can affect metabolic homeostasis and insulin resistance. Leptin and adiponectin are two of the most abundant adipocytokines produced by adipocytes, and their levels decrease in the lipodystrophic states.[10] Serum adiponectin levels correlate positively with insulin sensitivity[177,178] and are upregulated by PPARγ agonists.[179] Adiponectin acts by reducing hepatic gluconeogenesis (mainly via adiponectin receptor 2 and activation of AMPK phosphorylation) and increasing fatty acid oxidation in muscle (mainly via adiponectin receptor 1).[180] An animal study also demonstrated that adiponectin may also act in the hypothalamus (via adiponectin receptor 1) to activate insulin and leptin signaling pathways, thus promoting reduction of food intake.[181] Antiinflammatory effects of adiponectin have also been shown in various animal models of liver inflammation[81] and suggested by several observational studies in humans.[182]

In earlier animal models, it was shown that increased expression of adiponectin correlates with improved insulin sensitivity, with adiponectin decreasing insulin resistance by decreasing the triglyceride content of liver and muscle.[183,184] Although adiponectin or leptin alone partially improves insulin resistance in mouse models of lipodystrophy,[185,186] the combined administration of physiologic doses of both fully normalizes insulin sensitivity.[183] In patients with lipodystrophy, adiponectin levels are low in certain subsets of the disease, particularly in many patients with CGL1 and HALS,[187-189] and implicate hypoadiponectemia in the development of associated insulin resistance, hypertriglyceridemia, and fat redistribution.[190,191]

Serum leptin levels reflect the overall amount of adipose tissue in the body and are positively correlated with adiposity.[176] In addition to regulating food intake and increasing energy expenditure, leptin also plays an important role in the regulation of glucose homeostasis, possibly independently of its weight-reducing effects.[192] Aside from its actions in the central nervous system (CNS), leptin may exert its insulin-sensitizing effects peripherally by decreasing gluconeogenesis in the liver and adipose tissue, by exerting its lipolytic activity, and/or by increasing glucose utilization in skeletal muscle.[192] Leptin may also prevent the "lipotoxic" effects of intramyocellular lipid accumulation by activating fatty acid oxidation in skeletal muscle.[192,193] It has been shown that leptin levels are decreased in a significant proportion of patients with HALS[175] and that leptin administration improves metabolic manifestations of HALS in humans in the short and long term.[194-196] In generalized lipodystrophy, leptin concentrations are very low to undetectable, while in partial lipodystrophy they may vary from normal to low.[10] Leptin levels depend on several factors such as age, sex hormones, and fat mass. Moreover, serum leptin concentration may assist physicians in identifying and treating lipodystrophy disorders.[5,197] Leptin levels *per se*, however, should not be considered as a reliable and sufficient index to confirm or exclude lipodystrophy diagnosis.[2]

Inflammation

Inflammation in adipose tissue is likely to contribute to increased insulin resistance in the lipodystrophic state. Altered innate immunity and chronic inflammation appear to be strongly associated with insulin resistance in obesity and type 2 diabetes.[198] Inflammatory adipocytokines, such as TNF-α, IL-6, IL-8, macrophage inflammatory protein (MIP)-1α and 1β, monocyte chemotactic protein-1 (MCP-1; also known as CCL-2), plasminogen activator inhibitor-1 (PAI-1), angiotensinogen, retinol-binding protein-4 (RBP-4), and others have been implicated as the key regulators of insulin sensitivity.[179,199] The expression of several of these proteins, including TNF-α, IL-6, and IL-8, as well as macrophage markers (CD68, ITGAM, EMR1, ADAM8) and chemokines (MCP-1 and CCL-3), is increased in the subcutaneous tissue of patients with HALS.[200] In a small study of HALS, plasma PAI-1 was also found to be elevated, although its expression level in adipose tissue was not.[201]

Accumulating evidence supports an association between inflammation and insulin resistance. TNF-α mediates insulin resistance via reduction of insulin receptor kinase activity, induction of lipolysis, and downregulation of GLUT-4.[202,203] It may also induce apoptosis of adipocytes.[203] The impact of IL-6 on insulin resistance is less clear, but the majority of the evidence indicates that chronic elevation of IL-6 promotes hepatic insulin resistance and impedes differentiation of adipose tissue,[204] whereas acute elevation of IL-6 levels after exercise may promote improved glucose and lipid metabolism.[204] MCP-1 has been shown to induce insulin resistance by downregulation of GLUT-4, beta-adrenergic receptors, and PPARγ in mice. It is also associated with increased levels of atherosclerosis. Two pathways, the NF-κB pathway and the c-Jun NH_2-terminal pathway, are essential for mediating insulin resistance. Pharmacologic inhibition of the pathways has resulted in improved insulin resistance.[179,199]

Mitochondrial Stress, Oxidative Stress, and the Endoplasmic Reticulum

Mitochondrial defects have been considered as a central factor in NRTI-induced lipodystrophy. Mitochondrial dysfunction will lead to oxidative phosphorylation defects and ROS accumulation. Observational studies have shown that clinical conditions associated with increased ROS levels are also associated with increased insulin resistance.[174] Oxidative stress may also trigger β cell apoptosis and may contribute further to insulin resistance.[205,206] Angiotensin receptor blockers can attenuate oxidative stress and prevent further progression of insulin resistance.[207]

The ER plays an important role in regulating lipid, glucose, cholesterol, and protein metabolism. Stress on the ER luminal environment may generate an increased load of unfolded or misfolded proteins and may lead to adipocyte apoptosis, inflammation, and insulin resistance.[174] Seipinopathy has recently been identified as an ER stress–associated disease[208] and may contribute to insulin resistance in patients with CGL2.

Other Mechanisms

In addition to the mechanisms mentioned earlier, HAART may also contribute to insulin resistance by directly blocking glucose uptake (PIs) or by reducing phosphorylation of a key step in postreceptor insulin signaling (indinavir).[209,210] As mentioned, CGL2/BSCL2 is a severe form of lipodystrophy that is caused by loss-of-function mutations of the *BSCL2*/seipin gene and is accompanied by several metabolic disorders, including extreme insulin resistance and hepatic steatosis. Recent findings support that seipin downregulates glycerol-3-phosphate acyltransferases (GPATs). The latter are probably also responsible for the defective adipogenesis. Furthermore, GPAT3 deficiency is associated with significant improvement in insulin sensitivity and hepatic steatosis.[211,212]

Finally, patients with severe lipodystrophic states who have voracious appetites, supposedly because of leptin insufficiency, are theoretically more prone to these insults because overnutrition may aggravate central obesity and has been associated with higher levels of inflammation and ROS load.

TREATMENT OF SYNDROMES OF LIPODYSTROPHIES

Lifestyle modification, hypoglycemics, and lipid-lowering agents are generally required to treat metabolic disturbances associated with lipodystrophies. However, they commonly yield limited results. The development of new drugs targeted to specifically reverse insulin resistance is expected with great anticipation, including the potential use of adipocytokines such as leptin in certain subsets of patients with lipodystrophic syndrome.

Lifestyle Modification

There are limited data on the effectiveness of diet and nutrition support on body composition and metabolic abnormalities in patients with lipodystrophy; however, a balanced macronutrient intake is recommended.[2,213] The general clinical recommendations have been to follow the standard dietary advice regarding management of dyslipidemia, obesity, insulin resistance, and impaired glucose tolerance, with the goal of attaining ideal body weight. Supplementation with dietary fiber and fish oil containing high doses of omega-3 fatty acids should be encouraged.[214,215] For patients with severe hypertriglyceridemia, an extremely low-fat diet (preferably <15% of daily caloric intake coming from fat) should be advised. Several lines of evidence suggest that the Mediterranean diet, consisting of intake of plentiful fruits, vegetables, whole grains, olive oil, fish, and dairy products, and avoidance of red meat and saturated fats, may be of benefit in patients with HALS; specifically, insulin resistance improved and HDL cholesterol was increased.[216] Patients should also avoid alcohol consumption to prevent chylomicronemia, acute pancreatitis, and hepatic steatosis. For patients with fat atrophy, nutrition and caloric intake need to be assessed in detail.[215] In infants and young children with lipodystrophy, hyperphagia as a result of severe leptin deficiency is a significant issue, as it is associated with metabolic dysregulation, diabetes, hyperlipidemia, and hepatic steatosis. Consulting a dietitian with experience with this condition is recommended for this subpopulation.[2,73]

Studies evaluating the effect of exercise regimens involving resistance training, aerobic exercise, or stretching and relaxation techniques have all shown only modest benefit in improving body composition and metabolic abnormalities in HIV-infected patients.[217,218] Although both strength and endurance training improve peripheral insulin sensitivity, only strength training reduces total body fat in HIV-infected patients with lipodystrophy.[219]

In general, exercise should be advised in the absence of specific contraindications. On the contrary, individuals with specific subtypes of lipodystrophy (i.e., CGL4), who are predisposed to cardiac disorders, should undergo medical evaluation before initiating an exercise program.[2]

Overall, diet and increased physical activity of any kind are essential factors in managing lipodystrophy comorbidities and improving or preventing the clinical manifestations of lipodystrophy. Patients with lipodystrophy should also be advised on smoking cessation and optimal blood pressure control to minimize cardiovascular risk factors.

Management of Insulin Resistance

The treatment strategy for the management of insulin resistance in patients with lipodystrophy is, in general, not different from that in other states of insulin resistance. Traditional insulin sensitizers such as metformin and/or thiazolidinediones can be considered, along with lifestyle modifications. There are no known pharmacologic interactions between antihyperglycemic agents and antiretroviral agents.[220]

Metformin. Metformin, which acts by inhibiting gluconeogenesis in the liver and increasing peripheral glucose utilization, has shown efficacy in improving insulin sensitivity in patients with lipodystrophies.[221] It may also potentially improve fat redistribution in HALS, as indicated by a randomized controlled trial.[222] Other studies have cast doubt on the potential usefulness of metformin, however, by suggesting that metformin may lead to no changes in waist-to-hip ratio and may possibly cause further loss of limb fat.[222-224] Moreover, metformin, particularly in combination with exercise training, may be useful in HIV-infected patients with significant lipohypertrophy and minimal lipoatrophy. Metformin, in combination with lifestyle modifications, is considered as first-line pharmacotherapy to treat individuals with insulin resistance and diabetes. Furthermore, the US Food and Drug Administration (FDA) has approved metformin usage in pediatric patients 10 years of age and older, noting its efficacy and safety in this subpopulation.[2,73]

Thiazolidinediones. The thiazolidinediones (TZDs), which act by stimulating nuclear transcription factor PPARγ, have shown promise in treating patients with lipodystrophies.[225] TZDs result in improved insulin sensitivity, but data on fat redistribution and lipid profiles have been variable and conflicting. Although some studies show that TZDs may increase subcutaneous fat in patients with lipodystrophy,[223,226-229] other studies in patients with HALS showed no statistically significant difference in limb fat gain between rosiglitazone- and placebo-treated groups.[230,231] Rosiglitazone may also be associated with increased LDL and triglyceride levels, which makes it a less desirable drug to treat lipodystrophies. Pioglitazone, with its more favorable lipid profile, may have a more central place in the control of metabolic abnormalities associated with HALS. Randomized studies have demonstrated that treatment with pioglitazone can improve limb fat in HIV-infected patients, although patients may not perceive the clinical benefits.[228] Both pioglitazone and rosiglitazone are of benefit to the metabolic syndrome of HALS. In one placebo-controlled randomized study, treatment with pioglitazone during a 1-year period increased serum adiponectin levels and was as efficacious as treatment with rosiglitazone in improving insulin resistance in patients with HAART-induced metabolic syndrome, in addition to having more favorable outcomes on blood pressure and lipid profiles.[232] A recent study found that, in HIV-positive subjects treated with pioglitazone, administration of recombinant leptin (metreleptin) further reduced fasting insulin concentration and insulin resistance and attenuated postprandial glycemia.[233] These findings indicate that the improvements in hyperinsulinemia and insulin resistance from leptin therapy in HALS may be successfully combined with the increases in total body and peripheral fat induced by pioglitazone. TZDs can also lower blood pressure and improve endothelial function, therefore reducing overall cardiovascular risk in the HALS population.[234] According to the results from several studies, TZDs may improve the metabolic profile in individuals with partial lipodystrophy. Thus, these drugs are suggested for the management of the metabolic complications related to partial lipodystrophy. However, limited evidence exists regarding their use in generalized lipodystrophy, and they should only be applied cautiously in this subgroup.[2,235] More, larger, and longer randomized studies are needed in this area.

Other Treatment Strategies. Individuals with lipodystrophy and diabetes usually require combination therapy with insulin and metformin. Most lipodystrophy patients demonstrate severe insulin resistance and may need large doses. In cases where patients require daily large insulin doses (i.e., >200 units daily), concentrated forms of insulin such as U-500 regular insulin should be considered. The pharmacokinetics of long-acting insulins may be affected when they are injected into lipodystrophic areas. Their long duration of action requires the presence of subcutaneous adipose tissue.[2,73,235,236]

The new antidiabetic drug classes, such as sodium-glucose transporter inhibitors and glucagon-like peptide-1 receptor agonists, display significant renal and cardiovascular benefits, with improvements in cardiovascular outcomes and all-cause mortality, especially in high-risk diabetes patients.[237,238] However, their efficacy and safety in patients with lipodystrophy syndromes have not been systematically confirmed.

Bariatric surgery is the most effective possible weight-loss therapeutic strategy and also demonstrates weight loss–independent effects on glycemic control and metabolism. [239,240] A number of studies have been conducted to explore the impact of Roux-en-Y gastric bypass (RYGB) in patients with FPL. RYGB led to significant weight loss and metabolic improvements.[241-243] However, long-term controlled studies are needed to examine the health outcomes, as well as the overall impact and safety of this intervention, in these specific subpopulations.

Management of Dyslipidemia

The treatment of dyslipidemia in lipodystrophy should follow the same guidelines as in the general population. Lifestyle modification should be emphasized and attempted first. If ineffective, a change of antiretroviral treatment may be considered initially, followed by starting lipid-lowering medications in high-risk HALS patients. Lipodystrophy-related dyslipidemia can be difficult to treat, and multiple agents may be necessary to lower lipids to target ranges.[220] Extra caution may be necessary, given the potential drug–drug interactions among lipid-lowering agents and HIV-specific treatments.

Statins. Statins, such as 3-hydroxy-3-methylglutaryl coenzyme A reductase inhibitors, are normally used as first-line agents for hypercholesterolemia, especially for patients who have fasting triglyceride levels less than 500 mg/dL. Statins have antiinflammatory, antithrombotic, and endothelial effects that contribute to their overall beneficial effects on reducing mortality from cardiovascular disease. Extensive studies on the use of statins to treat the hyperlipidemia associated with HAART have demonstrated efficacy in lowering total and LDL cholesterol and triglycerides. Specifically, rosuvastatin and pravastatin have been shown to decrease total LDL cholesterol levels.[227,244] Among the statins, pravastatin may also increase subcutaneous and limb fat.[245] However, caution must be exercised in cases of coadministration of statins and HAART. Coadministration of PIs normally results in increased levels of statins, except for pravastatin. Therefore, simvastatin and lovastatin should be avoided in HIV-infected patients receiving PIs, whereas atorvastatin should be used with caution. A higher dose of pravastatin may be necessary to achieve optimal lipid-lowering activity in HALS,[246,247] and coadministration of statins with efavirenz reduces atorvastatin, simvastatin, and pravastatin serum concentrations, meaning that statins need to be administered at higher doses.[248] Tailoring statin therapy to the HAART therapy regimen is thus very important.

Fibrates and Omega-3 Fatty Acids. Fibrates and long-chain omega-3 fatty acids have been extensively used to treat severe hypertriglyceridemia, but they have not been formally studied in patients with lipodystrophy. However, both medications should be used in patients with elevated triglycerides, especially when triglycerides are higher than 500 mg/dL and may be considered for levels greater than 200 mg/dL.[2]

Combination therapy with fibrates and statins may be required to treat dyslipidemia to achieve lipid goals and should be used concomitantly with lifestyle modification.

However, caution regarding their use is advised, given the increased risk of hepatotoxicity and myopathy, especially in the presence of known myositis or muscular dystrophy, and in patients with renal insufficiency. Fibrates are normally well tolerated and efficacious in the context of HALS.[140] Head-to-head comparisons of the efficacy of fenofibrate versus gemfibrozil in HALS are lacking. Omega-3 fatty acids have also proved to be effective in reducing triglycerides in HALS.[249] They are generally well tolerated, but their use may be associated with increased LDL levels.[140,250]

In children and adolescents with lipodystrophy and very high levels of triglycerides, when lifestyle interventions are not sufficient, the use of lipid-lowering drugs should be considered. Fibrates are commonly used in children with severe hypertriglyceridemia who are at high risk of pancreatitis.[251] Omega-3 fatty acids may also prove beneficial.[251,252]. Fibrates alone or in combination with statins can effectively improve the lipid profile. However, data are limited in children, and physicians should pay attention to potential adverse effects.[252,253]

Nicotinic Acid. Nicotinic acid, or niacin, is effective for hypertriglyceridemia, but its use may be limited by adverse effects including flushing, rashes, pruritus, and exacerbation of insulin resistance and hyperuricemia. Extended-release niacin preparations are generally better tolerated in HIV lipodystrophy. The side effects can be controlled with daily aspirin intake.[140] Acipimox, a long-acting niacin analog, may also improve triglycerides and improve insulin sensitivity.[254]

In 2016, after reviewing the data of large cardiovascular outcome studies (HPS2-THRIVE, AIM-HIGH, and ACCORD), the FDA concluded that, when niacin extended-release tablets and fenofibric acid delayed-release capsules are coadministered with statins, the risks outweigh the benefits, and this combination is not recommended.[255-258]

Other Lipid-Lowering Agents and Novel Therapies. Ezetimibe, a cholesterol absorption inhibitor, might be useful in the treatment of statin-intolerant patients or in severe dyslipidemia associated with lipodystrophies.[140] Studies have shown that ezetimibe can provide incremental reduction in LDL cholesterol levels when combined with a statin, but a recent study suggested that the combination treatment may not provide additional reduction in cardiovascular risk.[259] Tetradecylthioacetic acid, cholestin, and L-carnitine have also shown efficacy in controlling dyslipidemia via unknown mechanisms,[140] but their use in HALS remains limited.

Treating extreme hypertriglyceridemia in lipodystrophy patients with conventional dietary and drug therapy may prove to be challenging. Novel lipid-lowering agents directed towards lowering triglyceride levels have been developed, and several potential therapeutic agents are under examination. Genome-wide association studies have uncovered potential targets in multiple circulating factors that may play a vital role in the regulation of lipid metabolism, hepatic steatosis, and insulin sensitivity. Furthermore, clinical pharmacology promotes the development of novel and promising therapeutic strategies, such as the antisense oligonucleotide-based therapies.[260]

Volanesorsen is a second-generation antisense oligonucleotide agent targeted to human apolipoprotein CIII (apoCIII) mRNA. ApoC-III is an important regulator of plasma triglyceride concentration. According to the results of phase III clinical trials, volanesorsen reduced triglycerides significantly compared to baseline.[261,262] Volanesorsen has been approved to treat patients with familial chylomicronemia syndrome.[263] The BROADEN study is an ongoing randomized, double-blind, placebo-controlled trial that enrolled patients with hypertriglyceridemia and FPL. The study aims to evaluate the safety and efficacy of volanesorsen in this subpopulation, and it is expected to be completed in the last quarter of 2021.

Moreover, inhibition of angiopoietin-like protein 3 and 4 affects lipid metabolism and is associated with low serum triglycerides.[264-267]

Trials involving ANPL-3 inhibition either in the form of monoclonal antibodies or antisense oligonucleotides are ongoing and may result in approval of novel treatments for hyperlipidemia. [268,269]

Patients with hypercholesterolemia who do not achieve sufficient LDL reduction despite receiving maximally tolerated first-line lipid-lowering treatment (namely statin drugs) may be prescribed additional therapy with ezetimibe or proprotein convertase subtilisin/kexin type 9 antibody inhibitor (PCSK9i).[270,271] Two PCSK9is have been approved in the United States and the European Union as adjuncts to dietary changes and maximal-tolerated statin therapy. Evolocumab (at a dose of 140 mg biweekly or 420 mg monthly) and alirocumab (75 mg/150 mg every 2 weeks or 300 mg monthly) are human monoclonal antibodies against PCSK9 that are administered subcutaneously. Both drugs are highly potent in reducing LDL (up to approximately 60% in addition to statin monotherapy) and the risk of major cardiovascular events, particularly in high-risk patients, in phase III studies.[272,273]

Another promising approach that is being examined for PCSK9 inhibition is inclisiran. Inclisiran is a chemically synthesized small interfering RNA molecule that reduces PCSK9 synthesis.[274] The ORION program includes several trials that examine the safety and efficacy of inclisiran. According to the findings of phase III placebo-controlled, double-blind, randomized clinical trials, ORION-10 and ORION-11, inclisiran at a dose of 300 mg every 6 months reduced LDL levels by approximately 50%.[275] It should be noted that inclisiran, because of its long duration of action, can be administered subcutaneously twice yearly, unlike conventional monoclonal PCSK9i. However, no available data exist regarding the efficacy and safety of these drugs in patients with lipodystrophy.

Bempedoic acid is a novel, once-daily, oral agent for treating hypercholesterolemia. It is an inhibitor of adenosine triphosphate citrate lyase, which is involved in the cholesterol synthesis pathway in the liver.[276] Bempedoic acid monotherapy was associated with LDL reduction up to 16.5% (vs. placebo) in patients with heterozygous familial hypercholesterolemia and/or atherosclerotic cardiovascular disease and up to 21.4% in patients with statin intolerance after 12 weeks of treatment.[277,278] Moreover, bempedoic acid administration, when added to maximally tolerated statin therapy, may reduce mean LDL by 18% (vs. placebo) in patients with heterozygous familial hypercholesterolemia and/or atherosclerotic cardiovascular disease and by 24% (vs. placebo) in patients with a history of statin intolerance.[279] A meta-analysis of seven randomized clinical trials has shown that bempedoic acid is an important option for patients at high cardiovascular risk and for those with statin intolerance, accompanied by an acceptable safety profile.[280] In 2020, bempedoic acid either as a monotherapy or as a combination with ezetimibe received approval (both in the United States and in the European Union) for use in patients with established atherosclerotic cardiovascular disease who require additional cholesterol lowering or in patients with heterozygous familial hypercholesterolemia.[281] Among the potential adverse events, elevated liver enzymes, tendon rupture, hyperuricemi,a and gouty attacks have been described.[281]

By the end of 2022, the randomized, double-blind, placebo-controlled, CLEAR Outcomes study is expected to be completed. The purpose of this phase III study is to examine the effects of bempedoic acid on major cardiovascular events in statin intolerant patients with or at high risk for cardiovascular disease (NCT02993406).

Finally, plasmapheresis is an option in patients with extreme hypertriglyceridemia associated with significant complications such as acute or relapsing pancreatitis who are unresponsive to conventional therapeutic agents. Plasmapheresis has been found to be effective; however, it must be repeated frequently, and long-term data are not available.[282,283]

Management of Human Immunodeficiency Virus–Infected Patients With Highly Active Antiretroviral Therapy–Induced Metabolic Syndrome

Growth Hormone and Growth Hormone–Releasing Hormone Analogs. Growth hormone (GH) replacement has been proposed to have a promising role in HALS treatment, in that this group of patients is prone to GH deficiency (GHD). It has been observed that basal GH concentrations, overnight GH secretion, and pulse amplitude are reduced in patients with HIV lipodystrophy,[284] although normal pulse frequency is maintained.[285] Relative GHD also appears to be common in HALS, as evidenced by decreased response to a standardized GH–releasing hormone (GHRH) arginine stimulation test.[286] Although the causative relationship between GHD and metabolic abnormalities is not well understood, interventions that normalize GH concentrations have demonstrated efficacy in improving metabolic abnormalities associated with visceral fat accumulation in the HIV-infected population.[285]

Treatment with high doses of GH (2–6 mg/day) has shown to effectively reduce visceral fat and improve lipid parameters.[287-289] However, its application is hampered by significant side effects, including fluid retention, arthralgia, myalgia, carpal tunnel syndrome, and worsening glucose control. There is also the theoretical concern that long-term GH therapy may increase the risk for cancer. In addition, high-dose GH replacement may lead to a further decrease in peripheral subcutaneous fat,[290] which is undesirable in this patient population from a cosmetic point of view. The effect of GH generally diminishes after discontinuation of treatment; however, improvement in facial lipoatrophy for up to 6 months after cessation of treatment has been reported.[291]

Increasing evidence demonstrates that physiologic GH replacement, with doses as low as 2 to 6 mcg/kg/day, can also effectively raise circulating IGF-1 levels and may provide similar benefits in visceral fat reduction but fewer adverse effects.[291-294] Although low-dose GH treatment did not result in worsened insulin sensitivity,[285] this potential side effect and the lack of durability with GH treatment limit its clinical application. GH therapy is not currently FDA-approved for treatment of HALS.

GHRH, the hormone that regulates GH secretion by the pituitary gland, has recently emerged as an alternative treatment option for HALS. GHRH augments endogenous GH pulsatility and may preserve the negative feedback of IGF-1 on the pituitary gland.[285] Initial recombinant forms used, such as Sermorelin or GHRH 1-29 (Geref), have been shown to increase lean body mass, decrease abdominal visceral fat, and decrease truncal fat without altering glucose levels.[286,295,296]

Tesamorelin (Egrifta), a GHRH analog, is the first FDA-approved medication for the treatment of HALS. Two large phase III clinical trials were designed to evaluate the efficacy and safety of tesamorelin, demonstrating evidence of benefit without affecting glycemic control; patients receiving tesamorelin experienced an average visceral fat reduction of 11% at 6 months, and 18% by 12 months, while preserving insulin sensitivity.[297] Trunk fat, waist circumference, and waist-to-hip ratio all significantly improved, and patients reported improved feelings about body image.[295] Treatment with tesamorelin is also associated with improvement of triglycerides and total cholesterol levels,[297] but its effect on HDL seems to be variable[297,298] and needs to be confirmed by long-term controlled studies. Adverse events are usually limited to arthralgia, myalgia, and local site irritation.[295] The current indication for tesamorelin, which is administered by subcutaneous injection of 1 to 2 mg/day in single or divided doses, is HIV-infected patients without active malignancy who are distressed by moderate to severe abdominal fat accumulation. Therapy should not be continued beyond 6 months if there is no treatment response. Similar to other interventions, such as lifestyle modification or metformin, the effect of GHRH analogs ceases to exist upon discontinuation, and while analogs are generally well-tolerated, long-term effects of treatment remain to be elucidated.

Human Immunodeficiency Virus–Associated Lipodystrophy Syndrome–Specific Treatment. In addition to the above-mentioned treatment options, HALS-specific options may also be valuable in the treatment of these patients.

Modification of Highly Active Antiretroviral Therapy. Interruption of antiretroviral therapy is associated with increased mortality and opportunistic infections. Therefore, it should be avoided. Instead, a careful evaluation for cardiovascular risk factors should be conducted before antiretroviral therapy is initiated, and the drug with the fewest metabolic implications and comparable efficacy should be selected. Once lipoatrophy or metabolic complications develop, switching from the offending drug to another agent may be an important strategy. However, the reversal is normally slow and gradual.

In the case of lipoatrophy, the treatment regimen with two thymidine analogs should generally be avoided. Switching to abacavir or tenofovir may partially restore subcutaneous fat.[299] Switching from a PI to an NNRTI or abacavir has not shown any beneficial effects in terms of improvement of lipoatrophy. Regarding metabolic abnormalities, switching from a PI to nevirapine or abacavir has generally resulted in improved total cholesterol and triglycerides, whereas switching to efavirenz has generated less consistent results.[300] Newer-generation PIs (e.g., atazanavir, darunavir, and saquinavir) are associated with favorable lipid profiles. However, because antiretroviral regimens containing PIs normally require low-dose ritonavir for its boosting effect, the impact of switching from one ritonavir-boosted PI to another may be modest.[220]

Uridine. Uridine is a pyridine precursor that reverses mitochondrial toxicity. It may have clinical value in treating HALS induced by pyrimidines such as zalcitabine and stavudine. Uridine can also reverse the cell depletion and lactic acidosis seen with zidovudine and lamivudine combination. It has no effect on lipoatrophy caused by didanosine, a purine analog. Uridine is generally well-tolerated.[158]

Management of Cosmetic Appearance

Autologous fat transplant and implantation of synthetic bulking agents have been used for the cosmetic correction of facial lipoatrophy and appear to be associated with improvements in quality of life. However, long-term, well-designed studies are needed to assess their efficacy and safety.[301] Occasionally, the fat harvested from HIV-infected patients with buffalo hump can cause hypertrophies in the transplanted sites (cheeks) and cause a disfiguring "hamster" appearance. The intradermal injections of synthetic agents (polylactic acid or New-Fill) have been shown to result in a more durable increase in total cutaneous thickness persisting up to 48 weeks.

The efficacy and the safety of surgical treatment of HIV-associated facial lipoatrophy using dermal fillers were assessed in a clinical trial. Four different dermal fillers (poly-L-lactic acid, calcium hydroxylapatite, polyacrylamide, and autologous fat) were examined. According to the results of the study, autologous fat transfer and permanent fillers achieved superior long-term durability for HIV-associated facial lipoatrophy, with high rates of facial volume restoration and patient satisfaction.[302]

Recently, a 10-year follow-up study demonstrated that highly purified liquid-injectable silicone was an effective long-term therapy for HIV-associated lipoatrophy. A microdroplet serial puncture technique was used, and small volumes of the product were injected at monthly or greater intervals to achieve the desired outcome. The most common adverse events that the patients experienced were excess fibroplasia of mild severity that could be treated and, to a lesser extent, severe acute inflammatory reaction presenting as facial edema without warmth or tenderness.[303]

Adipokines in Lipodystrophy

Leptin. A relatively large proportion of patients with lipodystrophy are found to have low leptin levels, including 20% to 30% of HALS patients[153] and the vast majority of patients with generalized lipodystrophy. Apart from its central and peripheral effects on satiety and glucose metabolism,[304,305] leptin has been associated with increased skeletal muscle lipoprotein lipase activity,[304] which may partially explain its ability to preserve lean tissue during weight loss.

The mechanisms through which leptin exerts its role remain under intensive investigation. Animal studies indicate that leptin acts mainly at the hypothalamus, particularly at neurons containing pro-opiomelanocortin and neuropeptide Y, to regulate food intake and fuel partitioning.[305] Functional MRI studies in humans confirm that leptin mediates its "adipostatic" effect through hypothalamic and other brain areas that are important in emotional and cognitive control.[306,307] Although animal and human studies indicate that leptin may also work peripherally (i.e., in the liver, muscle, and white adipose tissue) to affect lipid metabolism,[308,309] other studies suggest that these effects are largely mediated by the CNS.[310] Long-term leptin treatment may also attenuate β cell function and decrease glucose-induced insulin secretion,[305,311] but whether these effects are independent from reduction of insulin resistance remains to be seen.

Leptin Treatment in Generalized Lipodystrophy. The administration of recombinant leptin (r-metHuLeptin or metreleptin) has been tested in the treatment of congenital and acquired non–HIV-related lipodystrophies and has shown amelioration of metabolic abnormalities.[304,312] Several small, open-label studies show that subcutaneous injection of leptin (0.04–0.08 mg/kg/day) in patients with severe generalized lipodystrophy results in significant and sustained weight loss, with decreased fat and lean body mass. The weight loss is associated with a decrease in appetite, calorie intake, and resting energy expenditure. If excessive weight loss occurs, dosing should be decreased.[313-316] Metreleptin treatment has been associated with a significant reduction in hemoglobin A1c (HbA1c) levels, a reduction in fasting plasma glucose, and improvements in insulin sensitivity. Moreover, after metreleptin initiation, some patients were also able to discontinue insulin therapy.[317-319] Furthermore, metreleptin improved gonadotropin secretion, leading to the normal progression of female puberty and normalized menstrual cycles.[320-322]

Hypertriglyceridemia, usually refractory to traditional lipid-lowering agents, is commonly responsive to leptin treatment.[314] The liver volume decreases with leptin treatment, most likely as a result of decreased intrahepatic lipid content.[323,324] Transaminases and hepatocellular injuries that are associated with nonalcoholic steatohepatitis are also reduced.[323] In comparison with patients with generalized lipodystrophies, patients with familial partial lipodystrophy may have a less dramatic response to leptin treatment.[325,326] Because all these studies are uncontrolled and open label, it remains to be proven beyond any doubt whether the beneficial effects observed are r-metHuLeptin–specific.

Metreleptin has been approved in Japan as a leptin therapy for the treatment of lipodystrophy for several years.[327] Despite its declining use for metabolic disorders associated with partial lipodystrophy, the FDA advisory panel in 2014 suggested approval of metreleptin administration in adult and pediatric patients with generalized lipodystrophy. This announcement thus paved the way for a new modality in the treatment of this disorder, probably in the context of risk evaluation and mitigation strategy, given that the above uncontrolled studies have also demonstrated several potentially serious side effects. In individuals with generalized lipodystrophy, metreleptin in combination with dietary recommendations is the first-line treatment strategy for the disease-related metabolic and endocrine comorbidities. Metreleptin use may also be considered in children to prevent these disorders.[2]

Leptin Treatment in Partial Lipodystrophy. Some findings suggest that leptin replacement therapy may be beneficial in a subset of patients with severe partial lipodystrophy. Metreleptin appeared more effective in partial lipodystrophy patients with significant hypoleptinemia and severe metabolic disorders (such as HbA1c >8%, triglycerides >500 mg/dL).[5,197] Currently, metreleptin usage, both in CPL and APL, is off-label in the United States.

Leptin Treatment in Human Immunodeficiency Virus–Associated Lipodystrophy Syndrome. In addition to generalized lipodystrophies, we have reported a modest effect of leptin therapy on metabolic abnormalities in a randomized, placebo-controlled study in patients with HALS. Compared with placebo, r-metHuLeptin therapy administered at 0.02 mg/kg twice a day decreases body weight mass and truncal fat mass but not peripheral fat or lean body mass and improves fasting insulin levels, insulin resistance, and levels of HDL.[194]

Leptin treatment was associated with a 15% decrease in central fat mass, as well as significant improvements in glucose levels, insulin sensitivity, and fasting insulin, despite having no effects on LDL and triglycerides.[194] Other studies of longer duration confirmed these results, demonstrating a 32% decrease in visceral fat, increased hepatic insulin sensitivity, and improved dyslipidemia with metreleptin treatment.[195] The improvements in lipids and abdominal fat were comparable to those reported with metformin and thiazolidinediones in HALS patients and provide an advantage over GH replacement because leptin replacement has not been observed to induce glucose intolerance. Although no direct comparisons are available, the decrease of visceral adipose tissue and the lipid-lowering effect of leptin are either comparable or better than those reported for GHRH analogs.[293,297] Thus, recombinant human leptin holds promise as an agent that could improve HIV-associated lipoatrophy and features of the associated metabolic syndrome. Future randomized, placebo-controlled trials of adequate duration are needed to fully quantitate efficacy and clarify the side-effect profiles of metreleptin in HALS.

Clinical Use of Leptin: Benefits and Risks. Replacement of leptin may provide additional benefits beyond ameliorating metabolic abnormalities, which may include alleviation of the glomerular injury in humans with lipodystrophies[321,328] and improvement of pituitary-gonadal function in lipodystrophic patients with severe leptin deficiency.[322,329] It remains inconclusive, however, whether recombinant leptin therapy will affect such systems and/or bone density in the long term, given the uncontrolled nature of prior studies. Small human studies suggest that long-term treatment may not affect bone density in patients with generalized lipodystrophies with regular menses indicating normoleptinemia.[315,321,330]

Metreleptin combined with lifestyle modification is currently indicated for adults and pediatric patients with generalized lipodystrophy (congenital or acquired). The effectiveness and safety of metrelpetin for the treatment of partial lipodystrophy and liver disease, including nonalcoholic steatohepatitis, have not been established. Additionally, metreleptin is not indicated for patients with HIV-related lipodystrophy or metabolic disease (including hypertriglyceridemia and diabetes), without concurrent evidence of generalized lipodystrophy. The recommended daily dosage for patients with body weight 40 kg or under is 0.06 mg/kg/day at baseline, and may then be increased or decreased by 0.02 mg/kg to a maximum daily dose of 0.13 mg/kg. For patients with body weight more than 40 kg, the daily dosage for males is 2.5 mg/day, and then it may be increased or decreased by 1.25 to 2.5 mg/day to a maximum dose of 10 mg/day. The starting dose for females is 5 mg/day, which can be increased or decreased by 1.25 to 2.5 mg/day to a maximum amount of 10 mg/day. It should be noted that the effects of leptin do not appear to be sustained after the therapy is discontinued.[206,210,331,332]

Several patients experience side effects associated with metreleptin therapy. The most common and clinically significant adverse reactions are hypoglycemia (especially in insulin-treated patients), headache, abdominal pain, and decreased weight.[319] Other potential side effects of metreleptin treatment include deterioration of renal function[328] and possible occurrence of T-cell lymphomas. T-cell lymphoma has been reported in individuals with AGL, independent of treatment with metreleptin. Thus, further investigation is required. Physicians should evaluate the potential benefits and risks of metreleptin therapy in patients with significant hematologic abnormalities or AGL. Moreover, hypersensitivity reactions (including urticaria, anaphylaxis, generalized rash) and autoimmune disorder progression have been described in patients receiving metreleptin. *In vivo*, antimetreleptin antibodies with neutralizing activity have been identified. Individuals with loss of efficacy or severe infections during metreleptin treatment should be tested for neutralizing antibodies. The consequences of this neutralizing antibody response to leptin are not well characterized and may include inhibition of endogenous leptin activity and loss of metreleptin efficacy. However, potential risks are unclear and should be weighed against benefits.[320,332,334]

FUTURE PERSPECTIVES

Adiponectin

Adiponectin, as well as its receptors AdipoR1 and AdipoR2, are attractive future targets for drug development, given that levels of this hormone are lower in patients with HALS.[188] Based on the fact that adiponectin is decreased in lipodystrophic states and evidence from mouse studies showing that adiponectin administration can improve insulin sensitivity, dyslipidemia, sustained weight loss without reducing food intake, and production of proinflammatory cytokines,[335,336] adiponectin analog administration in replacement doses may prove to be an effective future treatment option. Because of its complex molecular structure, synthetic adiponectin is not yet available for therapy in humans. However, increasing adiponectin levels by pharmacologic means is likely to become a valuable addition to our armamentarium as a treatment option for lipodystrophy. Medications that increase endogenous levels of adiponectin in lipodystrophy, such as pioglitazone or INT-131, a selective PPARγ modulator currently in development, may prove useful as therapeutic possibilities, because they increase circulating adiponectin levels. Further research is needed to determine the efficacy and long-term durability of symptomatic improvement of lipodystrophy and its associated metabolic disorders, as well as short- and long-term morbidity and mortality.

  Outcome Studies of Pharmacologic Therapy for Hyperlipidemia, 416

Atherosclerosis is a chronic inflammatory disease of large- and medium-sized arteries that results from the deposition of lipids and lipoproteins in the intima of these vessels.[1,2] This process is a major cause of morbidity and mortality in the developed world, and the toll is particularly high in the diabetic population, accounting for approximately two thirds to three quarters of all diabetic deaths.[3] When combined with significant morbidity arising from ischemic injury and loss of limb perfusion, the impact of atherosclerosis on human health is enormous.[4] Improvements in the care of patients with and without diabetes, including the use of intensive lipid-lowering therapy, has led to significant reductions in mortality from cardiovascular (CV) disease in recent years.[5] This chapter will review basic principles of lipoprotein metabolism, focusing on the impact diabetes has on these lipid pathways. Data that address the value of lipid-altering treatments in reducing the burden of atherosclerosis in patients with and without diabetes will be presented. Finally, an approach to the management of patients with dyslipidemia will be outlined.

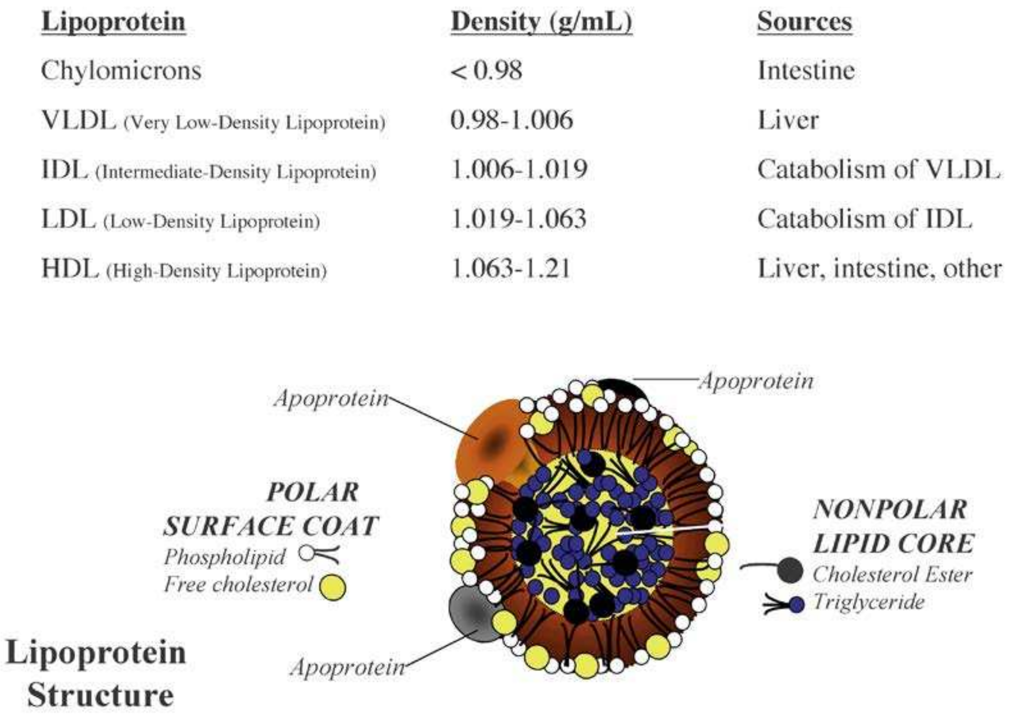
LIPOPROTEIN METABOLISM

Lipoproteins

The clinically reported serum triglyceride and cholesterol values represent the sum of the cholesterol and triglyceride contents of the circulating lipoproteins present in a volume of blood (expressed either as mg/dL or mmol/L). While knowledge of these total lipid values is very helpful in assessing CV risk, it is the distribution of cholesterol among the different lipoprotein fractions that is critical to any sophisticated understanding of atherosclerosis risk. Lipoproteins are structured to solve the problem of transporting highly hydrophobic lipids, such as cholesterol ester and triglyceride, in the aqueous environment of the blood. Because the bulk of lipoproteins are synthesized in the liver or gut, they must be moved via the bloodstream from these sites of synthesis to tissues where lipids will be taken up and utilized. By complexing neutral lipids with both proteins and more polar lipids such as unesterified cholesterol and phospholipids, the lipoprotein structure accomplishes this task. The more hydrophobic lipids are sequestered on the inside of the spherical lipoprotein, whereas more polar lipids and proteins decorate the outer surface (Fig. 25.1). In addition to solving the biophysical transport problem, the lipoprotein structure also enables particles to utilize a class of proteins known as *apoproteins* (Table 52.1) that serve as targeting molecules which interact with lipid-modifying enzymes (Table 25.2) or receptors and transporters (Table 25.3) critical for the normal functioning of the disparate lipoprotein classes. Complete loss of function mutations in the genes encoding apoproteins or the enzymes and receptors with which apoproteins interact (see Tables 25.1 to 25.3) are uncommon, but they can have a very significant influence on the circulating levels of lipoproteins in individuals with and without diabetes. As lipids play fundamental roles in a host of other cellular processes, mutations in lipid enzymes, receptors, transporters, and apoproteins can have profound effects on human biology beyond serum lipoproteins and CV disease, some of which are cited in Tables 25.1 to 25.3.

The nomenclature for most lipoprotein particles derives from the method by which they were originally identified and separated, that is, density gradient ultracentrifugation. For a brief period after the introduction of gel electrophoresis, lipoproteins were also classified by their migration properties on these gels, giving rise to alternative names such as *alpha* and *beta lipoproteins.* This period coincided with the identification of many of the clinical syndromes caused by abnormalities of lipid metabolism, so the names for some of these disorders still carry the signature of the electrophoresis era (e.g., *hypoalphalipoproteinemia* indicates low levels of the alpha-migrating or high-density lipoprotein [HDL]). Gel electrophoresis is rarely used in clinical laboratories today for standard lipoprotein measurements, though it may be used in specialty lipid labs to further subdivide classes of lipoproteins. As a consequence, the current medical literature has largely returned to the use of the density nomenclature to describe and characterize disorders of lipoprotein metabolism.

Although lipoproteins constitute a continuous spectrum of density within the plasma, they are commonly divided into five major classes (see Fig. 25.1). These are: (1) chylomicrons; (2) very low-density lipoproteins (VLDLs); (3) intermediate-density lipoproteins (IDLs); (4)



Lipoprotein	Density (g/mL)	Sources
Chylomicrons	< 0.98	Intestine
VLDL (Very Low-Density Lipoprotein)	0.98-1.006	Liver
IDL (Intermediate-Density Lipoprotein)	1.006-1.019	Catabolism of VLDL
LDL (Low-Density Lipoprotein)	1.019-1.063	Catabolism of IDL
HDL (High-Density Lipoprotein)	1.063-1.21	Liver, intestine, other

Fig. 25.1 The *upper panel* of the figure lists the density range that encompasses each lipoprotein class and the major tissue in which the lipoprotein is synthesized. The *bottom panel* is a graphic representation of a generic lipoprotein, emphasizing the spherical shape of the particle, the use of amphipathic apoproteins and polar lipids on the particle surface that interact with cells and the blood environment, and the sequestration of nonpolar lipids in the core of the lipoprotein. All lipoproteins share these general features, but they differ in size, lipid composition, and in the specific apoproteins embedded.

TABLE 25.1 Apolipoproteins of the Serum Lipoproteins

Apoprotein Ref	Major Lipoprotein	Functional Role (If Known)	Human Disease Association
AI[239]	HDL	LCAT activation	Cataracts, low HDL levels, CHD
AII[240]	HDL	Structural protein, ? function	No defect identified in a deficient subject
AIV[241]	HDL	Fat absorption, LCAT activation	? Altered plasma lipid and glucose levels
AV[242]	HDL, VLDL	TG metabolism	Hypertriglyceridemia
B_{100}[243]	LDL	VLDL and LDL synthesis	Hypobetalipoproteinemia (low LDL levels), familial defective apo B (high LDL levels)
B_{48}[243]	Chylomicron, chylo remnant	Intestinal fat absorption	Hypobetalipoproteinemia (low LDL levels)
CI[244]	HDL, VLDL, chylomicron	TG-rich lipoprotein uptake	Unknown
CII[245]	Chylomicron, VLDL	Lipoprotein lipase activation (LPL inhibition)	Chylomicron syndrome, pancreatitis
CIII[246]	Chylomicron, VLDL	Lipoprotein lipase inhibition	Hypertriglyceridemia
D[247]	HDL	? Activator of LCAT, neuronal function, cytoprotection	Unknown
E[248]	Chylomicron remnant, IDL, HDL	LDL receptor and LRP binding	Familial dysbetalipoproteinemia (type III), isoforms linked to Alzheimer risk
J (clusterin)[249]	HDL	Complement, chaperone, oxidative stress	Unknown
M[250]	HDL	? Cholesterol transport	Unknown

Modified from Genest J, Libby P, and Gotto AMJ. Lipoprotein disorders and cardiovascular disease. In: Zipes DP, Libby P, Bonow RO et al., eds, *Braunwald's Heart Disease: A Textbook of Cardiovascular Medicine* 7th ed. Philadelphia: Elsevier Saunders; 2005; pp. 1013–1033.

HDL, High-density lipoprotein; *LCAT,* lecithin cholesterol acyltransferase; *CHD,* coronary heart disease; *VLDL,* very low-density lipoprotein; *LDL,* low-density lipoprotein; *LPL,* lipoprotein lipase; *TG,* triglyceride; *LRP,* low-density lipoprotein receptor–related protein; *IDL,* intermediate-density lipoproteins.

low-density lipoproteins (LDLs); and (5) HDLs. Within these classes, further subdivision of lipoproteins can be made. In diabetics, a higher proportion of LDL is carried in a denser, smaller diameter subfraction that is called *small dense LDL* (sdLDL). HDLs are commonly divided into HDL_2 and HDL_3 subclasses, but some investigators have adopted a gel separation method to segregate HDL into a much large number of subtypes.[6] In this chapter, the density classification terminology will be used for all lipoproteins other than chylomicrons. A standard lipid profile, consisting of measured total serum or plasma cholesterol and triglyceride levels, combined with a measured HDL-cholesterol

TABLE 25.2 Lipid Transporters, Receptors, and Regulatory Proteins

Protein Ref	Function	Major Tissue Location	Human Disease Association
ABCA1[43]	Transporter of phosphatidylcholine and cholesterol	Ubiquitous (macrophages, liver, and gut)	Tangier disease (low or absent HDL)
ABCA3[251]	Transporter of lung surfactant	Alveolar type II cells	Neonatal respiratory failure
ABCA4[252]	Transporter of *N*-retinylidene-phosphatidylethanolamine	Retinal pigment epithelial cells	Stargardt's macular degeneration
ABCA12[253,254]	Transporter of ceramide esters	Keratinocyte	Harlequin and lamellar ichthyosis
ABCG1[255]	Transporter of cholesterol	Macrophages	Unknown
ABCG5[256]	Transporter with G8 of sterols	Enterocyte	Sitosterolemia
ABCG8[256]	Transporter with G5 of sterols	Enterocyte	Sitosterolemia
Apo E-R2/(LRP8)[257]	Apo E receptor, reelin receptor	Brain, testis	Unknown
CD36[258]	Fatty acid translocase, scavenger receptor	Macrophages, skeletal muscle, platelets	? Hypertriglyceridemia
CETP[259]	Cholesterol transfer in plasma	Liver, adipose	Hyperalphalipoproteinemia (high HDL)
HM74/GPR109A[260]	Receptor for nicotinic acid	Liver	Unknown
LDL-R[36]	Receptor for LDL	Ubiquitous (liver, adrenal)	Familial hypercholesterolemia (high LDL)
LOX-1[261]	Scavenger receptor for oxidized LDL	Endothelium, smooth muscle	Unknown
LRP1[262]	Endocytosis of many ligands, including chylomicron remnants	Liver, brain, placenta	Unknown
LRP2/megalin[263]	Endocytosis receptor, multiple ligands, including lipoproteins	Kidney, brain	Donnai–Barrow and facio-oculoacoustico-renal syndromes
MTP[264]	Lipid transfer in assembly of VLDL	Liver	Abetalipoproteinemia
NPC1[265]	Cellular cholesterol trafficking	Brain, liver	Niemann–Pick C disease
NPC1L1[266]	Cellular cholesterol trafficking	Hepatocyte, enterocyte	Unknown
PLTP[267]	Phospholipid transfer protein	Ubiquitous, liver	Unknown
PCSK9[268]	LDL-R regulating protein	Liver	High and low levels of LDL
SR-A[269]	Scavenger receptor, multiple ligands	Macrophages	Unknown
SR-B1[270]	Scavenger receptor, CE transfer	Liver, adrenal	Unknown
VLDL-R[257]	Apo E receptor, reelin receptor	Brain, heart, adipose, muscle	Cerebellar hypoplasia

Modified from Genest J, Libby P, and Gotto AMJ. Lipoprotein disorders and cardiovascular disease In: Zipes DP, Libby P, Bonow RO et al., eds, *Braunwald's Heart Disease: A Textbook of Cardiovascular Medicine* 7th ed. Philadelphia: Elsevier Saunders, 2005; pp. 1013–1033.

ABC, ATP-binding cassette; *ABCA,* a class of ABC transporter, *ABCG,* G class of transporter; *ACAT,* acyl cholesterol acyl transferase; *Apo E-R,* apo E receptor; *CETP,* cholesterol ester transfer protein; *LDL-R,* LDL receptor; *LOX-1,* lectin-like oxidized LDL receptors; *LRP,* LDL-R–related protein; *MTP,* microsomal triglyceride transfer protein, *NPCILI,* Niemann–Pick C1 like protein; *PLTP* phospholipid transfer protein; *PCSK9,* proprotein convertase, subtilisin/kexin type 9; *SR-A,* scavenger receptor A; *SR-BI,* scavenger receptor B1; *VLDL-R,* VLDL receptor; *HDL,* high-density lipoprotein; *LDL,* low-density lipoprotein; *VLDL,* very low-density lipoprotein; *CE*, cholesterol ester.

TABLE 25.3 Lipid Metabolism Enzymes

Protein Ref	Major Function	Major Tissue Location	Condition Caused by Altered Levels or Activity
ACAT1[44]	Cellular cholesterol esterification	Macrophages, steroidogenic tissues	Unknown
ACAT2[44]	Cellular cholesterol esterification	Liver, intestine	Unknown
Acid lysosomal lipase[272]	Hydrolysis of CE	Macrophage, adrenal, liver	CE storage disease, Wolman syndrome
Cholesterol 7-α hydroxylase[273]	Synthesis of bile acids	Liver	Cholestatic liver disease
Cholesterol 27-hydroxylase[273]	Synthesis of bile acids	Liver	Cerebrotendinous xanthomatosis
DGAT1[274]	TG synthesis	Intestine, liver, adipose, mammary	Unknown
DGAT2[274]	TG synthesis	Liver, adipose, mammary	Unknown
Endothelial lipase[275]	Hydrolysis of PL and TG	Liver, lung, kidney, endothelium	? Metabolic syndrome
Hepatic lipase[276]	Hydrolysis of TG	Liver	Elevated lipids, xanthomas, early atherosclerosis
HMG CoA reductase[277,278]	Cholesterol synthesis	Ubiquitous, liver	Unknown
Hormone-sensitive lipase[279]	Hydrolysis of intracellular TG	Adipose	Unknown
LCAT[280]	Cholesterol esterification (HDL)	Plasma, bound to HDL	Anemia, low HDL, renal failure, Fish eye disease (corneal opacities)
Lipoprotein lipase[281,282]	Hydrolysis of TG	Muscle, adipose	Chylomicronemia syndrome

ACAT, Acyl cholesterol acyl transferase; *CE*, cholesterol ester; *DGAT,* diacyl glycerol acyl transferase; *ER*, endoplasmic reticulum; *HMG*, 3-hydroxy-3-methylglutaryl; *LCAT,* lecithin cholesterol acyl transferase; *PL*, phospholipids; *TG*, triglyceride; *ACAT,* acyl cholesterol acyl transferase; *CE*, cholesterol ester; *DGAT,* diacyl glycerol acyl transferase; *HDL*, high-density lipoprotein.

level, is adequate to determine the relevant lipoprotein profile of most patients. Occasionally, specialty lipid assays are required to further characterize abnormal blood lipid values. A brief description of each of the five major lipoprotein classes is summarized in the following paragraphs. Readers interested in a more comprehensive introduction to lipoprotein metabolism should consult the lipid sections of *The Online Metabolic and Molecular Bases of Inherited Disease.* 8th ed.[7]

Chylomicrons. Chylomicrons derive from dietary fat and carry triglycerides throughout the body. Chylomicrons are generated in enterocytes in a process that appears to depend on lipin 2/3 phosphatidic acid phosphatase enzyme activity.[8] The major structural protein of chylomicrons is apolipoprotein (apo) B_{48}, a protein that is produced from apo B_{100} RNA by a unique editing process employed by gut cells that generates a protein that is 48% of the length of apo B 100.[9] Chylomicrons also contain other apoproteins, including members of the apo C and apo A family. These proteins can redistribute to other lipoprotein classes within the blood as chylomicrons transfer their lipid content to cells and interacting lipoproteins. Chylomicrons have the lowest density of all lipoproteins and will float to the top of a plasma specimen left in a refrigerator overnight, forming a cream-like layer. Owing to its large size, the chylomicron does not readily enter the artery wall and is therefore thought not to be atherogenic, but the atherosclerotic role of the triglyceride-depleted chylomicron remnant remains controversial. Triglyceride makes up most of the chylomicron and is removed by the action of an enzyme that is bound to the surface of endothelial cells, lipoprotein lipase (LPL). Patients deficient in this enzyme or its apoprotein cofactor (apo CII) have very high serum triglyceride levels and are at increased risk for developing acute pancreatitis. Inasmuch as insulin is also a critical cofactor for LPL activity, the majority of patients presenting with hypertriglyceridemic pancreatitis have poorly controlled diabetes as a major contributing factor to their delayed chylomicron clearance.

Very Low-Density Lipoproteins. VLDLs are also triglyceride-rich, but their triglyceride content is lower and their cholesterol content higher than those of chylomicrons. The protein composition of VLDLs also differs from chylomicrons in that the major structural protein is full-length apo B (apo B_{100}) as opposed to the truncated apo B_{48} form. Like chylomicrons, VLDLs are substrates for LPL-mediated triglyceride removal. The function of VLDL and chylomicrons is to carry triglycerides synthesized in the liver and intestines to capillary beds in adipose tissue and muscle, where they are hydrolyzed to provide fatty acids that can be oxidized to produce adenosine triphosphate (ATP) for energy production. Alternatively, if not needed for energy production, they can be reesterified to glycerol and stored as fat. After removal of their triglyceride, VLDL remnants (called *IDLs*) can be further metabolized to LDL. VLDLs serve as acceptors of cholesterol transferred from HDL, accounting in part for the inverse relation between HDL cholesterol and VLDL triglyceride. This transfer process is mediated by an enzyme called *cholesterol ester transfer protein* (CETP). The most common lipid abnormality seen in patients with type 2 diabetes is an elevated VLDL level, the causes of which will be discussed in the section on diabetic lipid abnormalities.

Low-Density Lipoproteins. LDLs are the major carriers of cholesterol in humans, responsible for supplying cholesterol to tissues with the highest sterol demands. LDLs are also the lipoproteins most clearly implicated in causing atherogenic plaque formation.[10] Circulating LDL levels can be increased in persons who consume large amounts of dietary saturated fat and/or cholesterol.[11] LDL levels are also elevated in those who have genetic defects that affect LDL receptor function (e.g., familial hypercholesterolemia [FH], proprotein convertase subtilisin kexin 9 (PCSK9) mutations, autosomal recessive hypercholesterolemia) or the structure of LDL's apoprotein, apo B, or who have polygenic disorders affecting LDL metabolism.[12] Circulating LDLs are taken up by the endothelium lining the artery wall, traverse it, and are deposited and trapped in the arterial intima. There, they may undergo oxidation or other biochemical modification, be taken up by macrophages, and stimulate atherogenesis. The association of total serum cholesterol with coronary heart disease (CHD) is predominantly a reflection of the strong correlation of LDL-cholesterol levels with total cholesterol levels in most humans. Studies in patients with diabetes have produced somewhat conflicting data on the prevalence of increased LDL levels, as defined by general population norms, but the preponderance of the evidence indicates that diabetics have LDL levels that are similar to those seen in well-matched, nondiabetic control populations. Given the greater risk of developing coronary artery disease (CAD) in individuals with diabetes, however, the National Cholesterol Education Program guidelines defined LDL levels above 100 mg/dL as being undesirable in those with diabetes. When judged by this stringent criterion, elevated LDL levels are extremely common in patients with diabetes. In addition, the LDL in individuals with diabetes is frequently smaller, denser, and more readily oxidized—all properties that are associated with a higher degree of atherogenicity.[13,14]

High-Density Lipoproteins. HDLs are the smallest of the lipoproteins; despite this, they carry a variety of apoproteins, including members of the apo A and C families. HDLs, unlike the other lipoproteins, are believed to function in humans primarily to return lipids from peripheral tissues to the liver and gut for excretion, rather than moving lipids from the gut organs to the periphery.[15] This perspective on HDL function is an oversimplification, as cell culture experiments indicate that HDL can donate lipids as well as pick them up; moreover, other components of blood in addition to HDL may be involved in the reverse transport process.[16-18] It has proven to be quite difficult to quantitate the net movement of cholesterol carried in HDL in and out of peripheral tissues in whole animals. Further complicating the issue is the fact that many of the standard laboratory animals used in metabolic studies carry most of their serum cholesterol in HDL rather than LDL, diminishing the relevance of studying their lipoprotein metabolism as a surrogate for understanding that of the LDL-rich human. Nevertheless, a considerable body of evidence suggests that HDL functions to protect tissues from unwanted accumulation of cholesterol. The mechanisms by which HDL may protect against atherosclerosis include its involvement in the reverse cholesterol transport pathway just described, as well as through contributions arising from its carriage of proteins that appear to have anti-inflammatory and antioxidant properties.[19,20] The unesterified cholesterol from tissues that is transferred to HDL is esterified by the action of lecithin cholesterol acyltransferase (LCAT) and stored in the central core of HDL. This esterified cholesterol can be transferred back to lower-density lipoproteins by the action of cholesterol ester transfer protein, or it may be removed at the liver by the action of a plasma membrane receptor called *scavenger receptor B-1.* A particularly effective reverse transport system is thought to explain, at least in part, the association of elevated HDL-cholesterol levels with a reduced risk of developing CHD. To date, however, therapies directed at raising HDL-cholesterol levels have failed to improve CV outcomes unless LDL cholesterol was also substantially lowered. In addition, studies of some genetic variants that appear to control HDL levels have been shown not to predict atherosclerosis risk, unlike genetic variants that control LDL levels, calling into question a causal role for HDL in impeding atherosclerosis.[21] Thus, the inverse association of HDL-cholesterol levels with atherosclerotic vascular disease risk, while epidemiologically well established, does not ensure that manipulations of HDL-cholesterol by therapeutic agents or lifestyle modifications will confer a CV benefit via that lipoprotein change. Exercise increases HDL levels; obesity, hypertriglyceridemia, and smoking lower them. Patients with diabetes, having higher body mass indices and hypertriglyceridemia, typically have lower HDL cholesterol levels than do nondiabetics, contributing further to the atherogenic lipid profile of the diabetic.

Metabolism of Lipids and Lipoproteins

The synthesis of lipoproteins in the liver and gut is a complex process regulated by hormonal and transcriptional networks that are affected by dietary intake of both lipid and carbohydrate. The disorders of carbohydrate and lipid metabolism caused by diabetes have both direct and indirect effects on lipoprotein metabolism. A brief summary of normal lipoprotein metabolism will be presented in this section, followed by a description of the impact of diabetes on these processes in the next section.

Following ingestion of a meal containing fat, the triacylglycerols (TAGs) are broken down by pancreatic triacylglycerol lipase to yield sn-2-monoacylglycerol and fatty acids. Ingested cholesterol is solubilized by bile salts into micellar structures, a step that is disrupted by bile acid resin binders. The lipids then transverse the enterocyte brush border membrane and are reassembled in the intestinal cell into a triglyceride-rich lipoprotein, the chylomicron. The role of transport proteins in the passage across the enterocyte membrane remains disputed, with evidence for both a passive diffusion and an active transport mechanism.[22,23] For cholesterol, a second transport step translocates the sterol into intracellular pools that can be accessed for lipoprotein packaging.[24] Niemann-Pick C1-like 1 protein appears to be required for this second step to occur and is the target of the cholesterol absorption inhibitor ezetimibe.[25,26] The internalized cholesterol is moved to the endoplasmic reticulum (ER), where the monoacylglycerol and fatty acids are also carried by transport proteins. The latter are recombined into TAG and bound by microsomal triglyceride transport protein (MTP). A second pathway of triglyceride synthesis uses acylation of glycerol-3-phosphate to phosphatidic acid, dephosphorylation to diacylglycerol (DAG), and then acylation of DAG to TAG. A high-density, protein-rich particle synthesized in the enterocyte, containing apo B_{48} and apo AIV, is then packaged with the absorbed lipids to generate the chylomicron.[27] This is then transported by vesicles to the basolateral membrane for exocytosis into the mesenteric lymph. The lipoproteins in the lymph enter the blood circulation via discharge from the thoracic duct.

Two ABCG half transporters, ABCG5 and G8, contribute to net cholesterol absorption in the gut through their ability to resecrete sterol that has been absorbed by the enterocyte back into the gut lumen, thereby reducing net sterol uptake.[28] The total amount of diet-derived TAG that is delivered to the circulation varies and is influenced by multiple factors, including the fat content of the diet, the amount of phosphatidylcholine in the intestinal lumen, and the expression level of apo AIV in the enterocyte. Overall, humans have a remarkable ability to absorb large quantities of both cholesterol and fat; 35% to 60% of ingested cholesterol is absorbed, with the amount inversely correlated with hepatic cholesterol synthesis. Up to 600 g of fat is absorbed with 95% efficiency. In individuals with normal lipid metabolism, the ingested fat is cleared from the enterocyte in less than 14 hours, forming the basis for measuring serum lipids after a fast of this duration. Circulating chylomicrons are subsequently cleared from the plasma by the action of endothelial-bound LPL, which cleaves the TAG, enabling the liberated glycerol and free fatty acids to move into the adjacent adipose or muscle tissue. The resulting chylomicron remnant particle can be further metabolized by lipases and appears to be retained in the hepatic space of Disse, where it can bind to heparan sulfate proteoglycans and acquire additional apo E. The acquisition of the apo E enables the remnant to be cleared efficiently by either the LRP1 or LDL receptor, but patients with diabetes have accumulation of remnants and slower lipoprotein hepatic clearance.[29,30]

The other major triglyceride-rich lipoprotein, VLDL, is synthesized in the liver and contains apo B_{100} rather than apo B_{48} as its major structural protein.[31] As with chylomicrons, VLDLs rely on MTP to combine lipids with the apo B protein to produce a nascent, lipid-poor lipoprotein.[32,33] This VLDL can be secreted from the liver or further lipidated to produce a mature VLDL. Individuals lacking MTP activity develop abetalipoproteinemia, a disorder characterized by erythrocyte acanthocytosis, anemia, steatorrhea, spinocerebellar degeneration, and fat-soluble vitamin deficiency. Acquisition of lipid by the mature VLDL appears to depend on triglycerides that are stored in the cytosol. Increased fatty acid delivery to the liver, from dietary sources or that released by lipase activity in peripheral tissues, stimulates VLDL production. After secretion of the mature VLDL from the liver, its triglycerides are initially removed by the action of LPL, and the resulting IDL can be further catabolized by hepatic lipase to produce mature, cholesterol-rich LDL.

Low-Density Lipoprotein Metabolism. There is still some dispute about whether mature LDL can be secreted from the liver rather than always being derived from the progressive removal of triglyceride from VLDL/IDL precursors.[34] However, the preponderance of data indicates that little if any LDL is directly secreted from the liver. Each LDL particle contains a single apo B molecule, which dictates that individuals heterozygous for apo B mutants will have two populations of LDL: one that carries a wild-type protein and one with a mutant protein. LDLs are utilized throughout the body as a source of exogenous cholesterol and are taken up by LDL receptors present at the plasma membrane. While LDL receptors are ubiquitous, the majority are expressed by the liver. The LDL receptor binds to both apo E– and apo B–containing lipoproteins. As the affinity of the receptor is higher for apo E than for apo B, apo E–containing lipoproteins, such as IDL, can compete with LDL for uptake by the LDL receptor. However, there are other receptors that can bind apo E–containing lipoproteins, permitting the clearance of the latter, but not that of LDL when LDL receptor activity is lost or diminished. Thus, mutations in the LDL receptor result in elevated LDL levels in the plasma, causing the autosomal codominant disorder FH, which is among the most common of Mendelian genetic disorders (see Genetics section later).[35] The elucidation of the cholesterol homeostatic mechanisms controlled by the LDL receptor constituted one of the major advances in our understanding of human physiology and disease.[36] The internalization of LDL by the LDL receptor leads to trafficking of the internalized lipoprotein to the endosome, where, after fusion with lysosomes, the sterol in the lipoprotein is released and shuttled to the ER. A sterol-sensing system in the ER regulates the movement of a membrane-bound transcription factor sterol response element binding protein (SREBP) from the ER to the nucleus.[37-42] SREBP works in concert with other transcriptional regulators to influence the expression of many of the cholesterol synthesis, metabolizing, and transport molecules, particularly in the liver. This elegant homeostatic system enables cells to reduce their *de novo* cholesterol synthesis when adequate sterol supplies are present and to increase synthesis and LDL receptor expression when cellular demands require more cholesterol.

High-Density Lipoprotein Metabolism. Although the relationship between elevated levels of HDL and lower rates of cardiovascular disease was recognized more than 65 years ago, a mechanism by which HDL causally protects against CHD remains to be elucidated. HDL are initially produced as lipid-poor phospholipid discs containing apolipoprotein AI. Following interaction with phospholipid/cholesterol transporters, primarily ABCA1, the nascent HDL particle acquires unesterified cholesterol from cellular stores.[43] For macrophages in particular, this cholesterol transport process constitutes a cholesterol efflux pathway that appears to be critical to the cell's ability to unload excess cholesterol acquired by phagocytosis of dead cells and by the unregulated uptake of lipoproteins by scavenger receptor pathways.[15] Cholesterol is stored in an intracellular lipid pool, having been esterified at its 3'OH position by the activity of acyl coenzyme A (CoA):cholesterol *O*-acyltransferase (ACAT).[44] A neutral cholesterol hydrolase cleaves the fatty acid from cholesterol ester to convert it back to free (unesterified) cholesterol when cellular signals call for the use or export of the sterol.[45] This free cholesterol can be shuttled to the plasma membrane, where it can be transported across by the action of ABCA1. The interaction of lipid-poor nascent HDL with ABCA1 appears to involve direct binding of apo AI to the transporter, but the actual lipid transfer process is poorly understood.[46-50] Once the unesterified cholesterol transfers to the nascent HDL, it can be reesterified by the action of LCAT and centralized in the lipid core of the growing HDL particle. This HDL particle can now interact with a second ABC transporter, ABCG1, and additional cholesterol can be acquired.[49] The role of ABCA1 is well established, as loss of its activity leads to Tangier disease (see Genetics section) and the absence or near absence of HDL in the plasma. Once the HDL has acquired sufficient cholesterol and esterified it, it can donate this lipid back to lower-density lipoproteins in the plasma, such as VLDL, through the activity of CETP. Alternatively, HDL can interact with a cellular receptor, SR-BI, to selectively transfer the cholesterol ester to cells, including the liver, where it could be excreted in the bile as cholesterol or one of its bile acid derivatives.[51] The protein component of HDL is cleared via the kidney, a process that appears to depend on the HDL being lipid depleted. The pathway just described, moving cholesterol from cellular storage pools to HDL and ultimately to the liver, is termed the *reverse cholesterol transport pathway.* The activity of this pathway has been postulated to explain at least in part the link between HDL levels and lower CHD risk. However, HDL also carries antioxidants and a host of proteins linked to complement and inflammation pathways that suggest it may be playing a more general role as a scavenger of molecules that stimulate inflammation. The complexity of its function has made targeting increases in HDL levels as a therapeutic objective very challenging. Both animal and human data have clearly established that simply raising HDL cholesterol levels does not ensure that a benefit on the atherosclerotic process will ensue.

KEY POINTS

- Lipoproteins vary in their lipid and protein composition forming a continuum of density from chylomicrons, which are the largest and least dense, to high density lipoproteins which are the smallest and most dense. They serve various biological functions but primarily are involved in moving cholesterol and triglycerides between tissues via the bloodstream. Both excess numbers and the inability to generate sufficient numbers of specific lipoproteins are associated with adverse health consequences.

DISORDERS OF LIPID METABOLISM IN PATIENTS WITH DIABETES

Type 1 Diabetes

Studies dating back more than three decades documented that individuals with type 1 diabetes have increased rates of CHD.[52-54] This risk was estimated to be 5- to 10-fold or greater than that seen in age-matched controls without diabetes. In the Diabetes UK cohort of 23,751 subjects who were diagnosed with insulin-dependent diabetes prior to the age of 30 years, for example, those individuals in the study who were 20 to 29 years of age at its onset had a standardized mortality ratio for ischemic heart disease of 11.8 for men and 44.8 for women. For those 30 to 39 years of age, the ratios were 8.0 and 41.6 for men and women, respectively.[55] More recent studies still show a significantly greater relative risk of atherosclerotic vascular disease in patients with type 1 diabetes, though the absolute risk has fallen substantially in that population in recent decades.[5,56,57] Despite the long and consistent reproducibility of this risk association, the pathophysiology underlying that relationship is still poorly understood. Unlike type 2 diabetes, where obesity and insulin resistance lead to changes in the standard lipid profile that are considered atherogenic, the type 1 diabetic who has not developed nephropathy and whose glucose is well controlled will typically have a normal serum lipid profile.[58] In the Diabetes Control and Complications Trial (DCCT)/Epidemiology of Diabetes Interventions and Complications study, the mean LDL-cholesterol in the group that was given intensive glucose-lowering treatment was 111 ± 29 mg/dL in women and 119 ± 31 in men; HDL-cholesterol levels averaged 63 ± 16 and 51 ± 14 for women and men, respectively. Serum triglyceride levels were also in the normal range, with women averaging 76 ± 37 mg/dL, and male values running moderately higher at 98 ± 67 mg/dL. These lipid values, which would be considered normal in most Western countries, did not differ significantly from those of the patients enrolled in the conventional glucose-lowering treatment group of the study. These findings make clear that the standard lipid profile provides few insights into the increased risk of CHD in type 1 diabetics.[59]

Surprisingly, epidemiologic risk-factor assessment of the correlates of CHD in type 1 diabetes shows a weak association to the one metabolic risk that predominates in the type 1 population: i.e., hyperglycemia.[60,61] It was therefore somewhat unexpected when a 17-year follow-up of the DCCT cohorts showed that the intensive treatment group had a 57% reduction in the risk of nonfatal myocardial infarction, stroke, or death from CV disease compared with the conventional treatment group (95% confidence interval [CI]: 0.21–0.88; $P = 0.02$).[62] Other studies of the impact of glucose control on CV outcomes have produced results that suggest that strict control of HbA1c levels is less important in reducing atherosclerotic vascular events or, in some circumstances, may even be detrimental.[63] Independent of the mechanism by which CV benefit is conferred, recent studies do suggest that current therapies are making a clear impact on reducing disease in type I diabetics.[5] Miller et al. reported a significant improvement in overall life expectancy in type 1 diabetics who were diagnosed between 1965 and 1980 versus similarly aged type 1 diabetics whose diagnosis was made between 1950 and 1964.[64] Although the data presented do not permit delineation of what accounts for this improvement, better care of ketoacidosis, renal disease, blood pressure and lipids are all strong contenders for contributors to the longevity improvement. With increasing numbers of patients experiencing the onset of type 2 diabetes in childhood or adolescence, it is now possible to compare outcomes of type 1 and type 2 diabetics in individuals whose diabetes was diagnosed early in life. Those with early-onset type 1 diabetes fare significantly better than those with early-onset type 2 diabetes, and a clear difference in CV death has been observed.[65] Finally, a study of diabetes-related complications, not specific as to type 1 or type 2, but likely predominantly representing type 2 diabetics, did find a substantial reduction in major complications of diabetes between 1990 and 2010, with a reduction in acute myocardial infarction showing the largest improvement.[66]

Type 2 Diabetes

There are alterations in multiple lipoprotein metabolism pathways in type 2 diabetics that lead to the typical abnormal lipid profile commonly seen. This profile includes hypertriglyceridemia secondary to high VLDL levels, as well as increased amounts of sdLDL and lower levels of HDL cholesterol. LDL-cholesterol levels are typically not higher in diabetic populations when compared with well-matched nondiabetic subjects. In an elderly Finish population, for example, approximately 30% of diabetic subjects had serum triglyceride levels greater than 200 mg/dL compared with 13% of nondiabetic subjects. HDL cholesterol levels were less than 35 mg/dL in about 25% of diabetics compared with 12% of nondiabetics. In this study, elevated LDL levels as defined by an LDL greater than 130 mg/dL were actually more prevalent in the nondiabetic population than in those with diabetes.[67,68]

The causes of classic diabetic dyslipidemia are only partly understood. Individuals with insulin resistance and type 2 diabetes overproduce mature VLDL in the liver. This is accompanied by a slower clearance of triglyceride-rich lipoproteins via reduced activity of LPL. Coupled with decreased receptor uptake of the remnant and IDL particles that form after LPL partially depletes VLDL of its triglyceride, diabetes produces substantial elevations in serum triglyceride levels. Production of sdLDL appears to be tightly linked to the resulting hypertriglyceridemia insofar as CETP exchanges triglyceride from VLDL for cholesterol ester from LDL, producing a triglyceride-enriched LDL.[69] This lipoprotein appears to be a preferred substrate for hepatic lipase, which hydrolyzes the triglyceride to produce an LDL that is smaller, lower in cholesterol ester content, and higher in density than LDL produced in the absence of excess VLDL. The diabetic with increased sdLDL levels has a higher LDL particle number for an equivalent serum LDL-cholesterol concentration than does an individual with normal LDL. This increased particle number, whether measured by nuclear magnetic resonance assays or serum apo B levels, is associated with an increased risk of CAD.[14]

Thus, the central metabolic change that accounts for much of the diabetic dyslipidemia is the overproduction of VLDL by the liver. The molecular mechanisms accounting for VLDL overproduction are not fully elucidated, but there is evidence that insulin activates a phosphatidylinositol-3 kinase pathway that inhibits apo B secretion while activating a mitogen-activated protein kinase (MAPK) that downregulates MTP expression.[70,71] Insulin effects on transcriptional regulators of VLDL secretion may also be involved. *In vivo* metabolic studies suggest that the prevalence of hypertriglyceridemia and low HDL-cholesterol levels is higher in diabetics who are insulin-resistant as opposed to insulin-deficient, accounting for the higher prevalence of these disorders in patients with type 2 versus type 1 diabetes.

KEY POINTS

- Normal body mass individuals with type I Diabetes commonly have a normal lipid profile with neither high levels of LDL or VLDL nor low levels of HDL. Patients with type 2 diabetes, particularly those with significant elevations in BMI, often have increased levels of VLDL (serum triglycerides are elevated) and lower levels of HDL cholesterol. The overall CV risk of those with type 2 diabetes is greater than those with type 2 diabetes, but both groups are higher risk than those without diabetes

GENETIC BASIS OF LIPID DISORDERS

Although metabolic disorders associated with diabetes, hypothyroidism, and nephropathy can exacerbate or even cause hyperlipidemia (Table 25.4), a substantial number of dyslipidemic individuals have none of these problems. Individuals with the greatest deviation from normal levels of lipoproteins often have a single gene defect that is responsible for their lipid disorder. The vast majority of hyperlipidemic patients, however, do not have a monogenic defect. Rather, they are most likely to have a polygenic disorder and an additional contribution from environmental factors (e.g., excessive saturated fat intake for high LDL levels; obesity or smoking for lower HDL levels). Currently, a genetic diagnosis is rarely required to enable appropriate lipid care to be given. Nevertheless, the identification of the causes of monogenic lipid disorders has been critical to our understanding of both normal and abnormal lipoprotein physiology. The lipid disorders with the greatest impact on developing CAD risk are those that increase the serum LDL level or reduce the HDL level, and these are briefly presented next.

TABLE 25.4 Secondary Causes of Hyperlipidemia and Dyslipidemias

Metabolic/hormonal	Diabetes
	Hypothyroidism
	Lipodystrophy
	Polycystic ovarian disease
Hepatic	Primary biliary cirrhosis
	Other forms of cirrhosis
Renal	Chronic renal failure
	Nephrotic syndrome
Dietary	Alcohol
	Foods highly enriched in cholesterol and saturated fat
Medications	Estrogens
	Glucocorticoids
	Anti-HIV– treatments, especially protease inhibitors
	Oral androgens and anabolic steroids
	Thiazide diuretics
	Beta-blockers
	Retinoic acid
	Antipsychotics

Monogenic Low-Density Lipoprotein Disorders

The molecular basis of four monogenic disorders that primarily affect LDL levels have been characterized: (1) FH, (2) familial defective apo B, (3) autosomal recessive hypercholesterolemia, and (4) PCSK9 mutations. These disorders illustrate distinct mechanisms leading to elevated LDL levels.

Familial Hypercholesterolemia. FH is one of the most thoroughly studied and common genetic disorders of mankind. Recent analyses have suggested the prevalence of individuals carrying a mutation in one allele encoding the LDL receptor is approximately 1 in 300, considerably higher than the prior estimates of 1 in 500.[72] These mutations results in defective clearance of LDL from the blood and a rise in serum total and LDL cholesterol levels. The elucidation of this defect and its associated cell biology led to insights into the homeostatic control of cholesterol metabolism that transformed the lipid field.[35,36] Well over 1000 individual mutations in the LDL receptor have now been identified. The gene, located on chromosome 19 and spanning 45 kb, has 18 exons that encode a mature protein of 839 amino acids. The inheritance of the disorder is autosomal codominant. Heterozygous patients typically have LDL-cholesterol levels in the 200 to 500 mg/dL range, and the rare homozygous FH patient usually has an LDL-cholesterol well above 500 mg/dL. Heterozygous patients commonly have tendon xanthomas and premature CAD, whereas these are universal in the untreated homozygous individual. Mutations in the LDL receptor have

TABLE 25.5 **3-Hydroxy-3-Methylglutaryl Coenzyme A Reductase Inhibitors (Statins): Key Properties of Clinical Interest**

Statin	Atorvastatin	Fluvastatin	Lovastatin	Pitavastatin	Pravastatin	Rosuvastatin	Simvastatin
Dose (typical range for agent)	10–80 mg	20–80 mg	20–80 mg	1–4 mg	20–80 g	5–40 mg	10–80 mg*
LDL-C reduction	38%–54%	17%–33%	29%–48%	31%–41%	19%–36%	42%–63%	28%–48%
Cytochrome P450 metabolism	3A4	2C9	3A4	2C9, 2C8	None	Some 2C9	3A4, 3A5
Renal excretion of absorbed dose	2%	<6%	10%	15%	20%	10%	13%
Mortality or CHD event benefit shown	Yes	No	Yes	No	Yes	Yes	Yes
Generic available	Yes	Yes	Yes	No	Yes	Yes	Yes

*Though approved at 80 mg, the US Food and Drug Administration has issued a warning about the use of this dosage due to higher levels of myopathy.

LDL-C, Low-density lipoprotein–cholesterol; *CHD,* coronary heart disease.

been described that affect multiple aspects of receptor biology, ranging from defective LDL binding to abnormal trafficking of the receptor to the plasma membrane. The effect of all of these mutations is to reduce LDL and IDL clearance from the blood. The latter effect results in an enhanced conversion of IDL to LDL. The net result is markedly elevated LDL cholesterol levels in the blood and a strong predisposition to early CHD if the disorder is not treated. FH heterozygotes typically respond well to 3-hydroxy-3-methylglutaryl CoA (HMG-CoA) reductase inhibitors (statins), though additional therapies may be needed to reach desirable LDL levels, especially in those with the highest pretreatment LDL values. FH homozygotes respond poorly to reductase inhibitors alone and inevitably develop early atherosclerotic vascular disease unless much more aggressive treatment methods, such as LDL apheresis, are utilized. Recent advances in therapeutics, however, have offered hope for less arduous forms of treatment. The finding that many patients previously assumed to have homozygous FH in reality had compound heterozygous FH, with one partially functioning LDL receptor allele, led to the finding that PCSK9 inhibitors can produce substantially better results in those patients than statins, presumably due to better recycling of the functioning LDL receptors.[73-76] Two specific therapies for FH homozygotes have been approved by the US Food and Drug Administration (FDA): one an oral drug targeting microsomal triglyceride transport protein (lomitapide) and the other an antisense therapy directed against apo B (mipomersen).[77-80] LDL levels were reduced by 25% to 36% with mipomersen and approximately 50% with lomitapide, both outperforming the effect of statins on the LDL levels in these rare patients. However, both drugs appeared to lead to liver fat accumulation, which contributed to the withdrawal of mipomersen from the market. Orphan disease pricing made their use even in the rare FH homozygous patient population very difficult. A trial of a novel monoclonal antibody targeting ANGPTL3 inhibition (see section on ANGPTL3 later) has also recently shown promising effects in the FH homozygous population.[81]

Familial Defective Apolipoprotein B. Familial defective apo B (FDB) is an autosomal codominant disorder caused by mutations near the C-terminus of apo B.[82,83] Apo B is a 4536–amino acid protein encoded by a gene on chromosome 2 that is composed of 29 exons. The most commonly identified mutation in FDB affects an arginine at position 3500 that is mutated to either a glutamine or tryptophan. Most individuals with FDB are heterozygous for their mutation, and there is only one molecule of apo B per LDL particle, so the LDL in the serum of these individuals is a mixture of normal LDL and FDB LDL. The LDL containing the defective apo B does not bind normally to the LDL receptor and is therefore cleared more slowly. The explanation for the lower receptor affinity of LDL carrying the FDB mutations is not known with certainty. There is evidence, however, of a molecular interaction between the arginine at position 3500 and tryptophan at 4369 that appears to be necessary for the adoption of an apo B conformation recognized by the LDL receptor. Patients with FDB have elevations in their LDL levels that fall within the range of those seen in FH heterozygotes, but the mean is generally lower than the mean in FH cohorts. There is considerable variability in both genetic populations, however, making generalizations about the diagnostic value of this measurement not very useful. Tendon xanthomas are common but not universal, and premature CAD is prevalent. Treatment with reductase inhibitors or other standard LDL-lowering drugs is typically quite effective in FDB patients.

Autosomal Recessive Hypercholesterolemia. Studies of families in which LDL levels were inherited in an autosomal recessive pattern led to a successful genetic linkage analysis that mapped the genetic defect in these families to the short arm of chromosome 1. Candidate gene sequencing led to the identification of mutations in a gene now called *LDLRAP1*, also known as *autosomal recessive hypercholesterolemia* (*ARH*), comprising nine exons and eight introns. Patients diagnosed with ARH to date have been clinically similar to patients who are homozygous for LDL receptor mutations in that they have markedly elevated LDL cholesterol levels (typically >500 mg/dL), tendon xanthomas, and premature coronary atherosclerosis.[84] The autosomal recessive mode of inheritance is an important differentiating factor between ARH and FH, as is greater LDL receptor activity, as measured in cultured fibroblasts taken from the patients. The defect in ARH patients appears to affect liver cholesterol metabolism disproportionately, and current data indicate that the *ARH* gene product likely serves as an adaptor protein required for LDL receptor internalization via clathrin-coated pits.[85,86] ARH patients do respond to HMG CoA reductase inhibitors, but this treatment is usually inadequate to control their markedly elevated LDL-cholesterol levels, making them candidates for lomitapide and other combination lipid therapy.[87]

Proprotein Convertase Subtilisin Kexin 9 Mutations. PCSK9 is a 72-kD protease that is highly expressed in the liver and regulates the levels of LDL receptors acting at the plasma membrane.[88,89] Gain-of-function mutations in PCSK9 result in lower LDL receptor levels, whereas loss-of function mutations increase those levels. Serum LDL levels are inversely related to liver LDL receptor expression; the activity of the latter clears the former from the circulation. Thus, gain-of-function mutations are associated with higher serum LDL levels and increased risk of CHD, and loss-of-function mutations result in lower LDL levels and decreased CHD risk. The role of PCSK9 in lipid metabolism was originally recognized when it was discovered that specific heterozygous mutations in the protein were associated with autosomal dominant hypercholesterolemia. Approximately 1 in 50 Black Americans has one of two nonsense mutations in PCSK9, causing

LDL-cholesterol levels to fall approximately 30%. White Americans can carry a missense mutation that reduces LDL-cholesterol by approximately 15%. Individuals with complete loss of PCSK9 activity have extraordinarily low levels of LDL-cholesterol but appear to be otherwise normal. The mechanism by which PCSK9 regulates LDL receptor activity is still being elucidated, but it appears that the protease can bind to the receptor, targeting it for degradation in the lysosome. This action does not depend on the protein's enzymatic activity, and exogenously administered PCSK9 can reduce LDL receptor expression and increase serum LDL-cholesterol levels, while approaches that reduce the amount of circulating PCSK9 have the opposite effect. The mechanism by which PCSK9 works made it an extremely attractive target for pharmaceutical intervention, and multiple agents that inhibit this protein have been developed as LDL-cholesterol–lowering therapies (see Diet and Drug Treatment section of this chapter).

ANGPTL3 Mutations. *ANGPLT3* is hepatically-derived circulating protein that inhibits both LPL and endothelial lipase. Mutations in this gene were first discovered to confer low plasma lipid levels inherited in a recessive manner in animal models, and resequencing of *ANGPLT3, ANGPLT4,* and *ANGPLT5* in the Dallas Heart Study identified multiple rare synonymous variants associated with low plasma triglyceride concentrations.[90,91] Exome sequencing in 2010 identified mutations in *ANGPTL3* as the cause of low LDL, HDL, and triglyceride levels in two siblings.[92,93] Studies to date suggest that mutations in *ANGPTL3* may cause a significant percentage of hypolipoproteinemia not explained by *APOB* mutations, particularly in the context of low total cholesterol and HDL levels. Properties of this protein have made it an attractive target for novel lipid-lowering therapeutics, and a recent trial of a monoclonal antibody (evinacumab) targeting ANGPTL3 resulted in significant LDL lowering in an FH homozygous population.[81]

Monogenic High-Density Lipoprotein Disorders

Three distinct monogenic disorders cause markedly reduced levels of HDL in the plasma by different mechanisms. They are: (1) Tangier disease, (2) LCAT deficiency, and (3) apo AI mutations.

Tangier Disease. Tangier disease was first recognized in 1960 in a sibling pair living on Tangier Island in the Chesapeake Bay in Virginia. Enlarged, yellow-orange tonsils and little or no circulating HDL cholesterol are the classic findings in the disorder. Subsequently, cases have been identified in which the presenting symptom was a peripheral neuropathy. Patients may also have hepatosplenomegaly. Serum LDL and total cholesterol levels are usually quite low, while serum triglyceride values are moderately elevated. Tangier disease is an autosomal recessive disorder. The cause of Tangier disease was identified by several groups following mapping of the gene defect to chromosome 9. Candidate gene analysis in the appropriate genetic interval identified mutations in an ATP-binding cassette (ABC) transporter as the cause. The transporter, now called *ABCA1* (ATP-binding cassette, subfamily A, member 1), is a full-length ABC transporter transmembrane protein that is predicted to span the plasma membrane 12 times. ABCA1 is a 2261–amino acid protein encoded by a gene spanning 50 exons. Approximately 100 mutations in the gene have been identified to date.[50,94] ABCA1 mediates the efflux of cholesterol from cholesterol-enriched cells when stimulated by the major apoprotein of HDL, apo AI.[95] This activity is lost in Tangier patients and is reduced by approximately half in carriers of one abnormal *ABCA1* allele. The mechanism of the movement of cholesterol from inside the cell to outside the cell has not been established. Individuals with Tangier disease, as well as heterozygous carriers of ABCA1 mutations (a disorder called *familial hypoalphalipoproteinemia*), appear to have increased risk of premature coronary disease. There is no specific therapy for this disorder.

Lecithin Cholesterol Acyltransferase Deficiency. The esterification of free cholesterol in circulating lipoproteins is catalyzed by a plasma enzyme called *lecithin cholesterol acyltransferase.* Two clinically separable syndromes result from a deficiency of LCAT. Fish-eye disease is due to a partial deficiency of LCAT, with patients presenting with dense corneal opacities and very low HDL-cholesterol levels. Familial LCAT deficiency arises from a nearly completely absence of LCAT activity and produces a more severe syndrome characterized by corneal opacities, anemia, and proteinuric renal failure.[96] The serum lipid and lipoprotein profile in the more severe disorder is characterized by normal or increased triglyceride levels, reduced LDL-cholesterol values, and markedly diminished HDL levels. The gene encoding LCAT is located on chromosome 16 and is composed of six exons. Cleavage of a signal peptide of 24 amino acids converts the proenzyme from a 440–amino acid precursor to the final 416–amino acid glycoprotein that circulates in the plasma. When unesterified cholesterol from tissues is transferred to HDL, either by passive diffusion or by ABCA1-mediated lipid transport, LCAT's activity esterifies the transferred cholesterol, trapping it in the HDL core. Because cholesterol ester is more hydrophobic than unesterified cholesterol, it is energetically unfavorable for the cholesterol ester to transfer back to the cell of origin. These steps of cholesterol transfer and esterification are the initial events in the reverse cholesterol transport pathway whereby cholesterol is moved from peripheral tissues back to the liver. Apo AI is the major activator of LCAT activity, accounting for the predominant effect of the enzyme deficiency on HDL levels. LCAT does, however, contribute to esterification of cholesterol in lower-density lipoproteins as well. Despite very low HDL levels, patients with either fish-eye disease or familial LCAT deficiency do not seem to have a predilection for very early coronary atherosclerosis. The small number of patients with the disease, some of whom have been found to have CHD, makes it difficult to determine if the risk of coronary atherosclerosis is substantially altered by the enzyme deficiency. There is no specific treatment for LCAT deficiency. Corneal and kidney transplantation are performed in these patients to ameliorate their major clinical disabilities.

Apolipoprotein AI Mutations. Apo AI is the major structural protein of HDL. The gene encoding apo AI is located on chromosome 11 and comprises four exons. Following cleavage of the signal and prohormone sequences, a 243–amino acid mature protein is produced. The protein has multiple repeats of an amphipathic helical structure that enables it to interact with both lipid and aqueous environments. Mutations that cause profound alterations in apo AI structure or expression have been reported, though they are extremely rare.[97-100] The individuals carrying these mutations have virtually no circulating HDL and typically develop early CHD. There are, however, a number of case reports of apo AI mutations that are not associated with early CHD. Corneal opacities and xanthomas have been documented in many, but not all, individuals with major apo AI mutations. Most patients harboring these mutations have been found to be homozygous for the gene defect, usually as a result of consanguinity. Heterozygotes carrying these mutations commonly have half-normal HDL-cholesterol levels, although cases with greater reductions in HDL levels have been reported, suggesting that some mutations may exert a dominant negative effect. HDL typically contains four apo A molecules per particle (either four apo AI or two apo AI and two apo AII proteins), so a heterozygous individual carrying an expressed apo AI mutant would have at least one mutant apo AI on most HDL particles. The atherosclerosis of individuals with structural mutations in apo AI appears to be much more pronounced than that seen in patients with either LCAT deficiency or Tangier disease. No specific therapy is available for this disorder, but aggressive LDL lipid-lowering therapy is justified.

Polygenic Lipid Disorders

Approximately 50% of the total interindividual variation in serum lipid levels is attributed to heritable factors.[101] Several GWAS studies have been conducted to identify genetic variants that contribute to population-wide lipid variability. One of the early, large lipid GWA studies was conducted in approximately 10,000 individuals and identified a total of 31 genetic loci associated with HDL levels, 22 loci associated with LDL levels, 16 loci associated with triglyceride levels, and 39 loci associated with total cholesterol levels; these results accounted for approximately 25% to 30% of the genetic component of these lipid traits, suggesting many lipid associated genetic variants remain to be found.[102]

A main finding of lipid GWA studies has been that genes which confer monogenic lipid disorders also harbor commonly occurring genetic variants with more modest effects on lipid levels.[103,104] The implications of genetic variants discovered in gene regions without known effect on lipid biology are less clear. Novel biology has been revealed through the functional characterization of genetic variants discovered in the *SORT1* and *TRIB1* genes, but more work is required to understand the effect of many variants discovered through GWA studies.[105,106]

Findings from GWA studies have also been used to test hypotheses within lipid biology. If genetic variants contribute to serum lipid levels, and serum lipid levels contribute to CV risk, then genetic variants for lipid levels should influence CV risk. In 2012, Voight and colleagues found no relationship between genetic variants associated with HDL levels and myocardial infarction.[107] This experiment has contributed to the debate as to whether HDL directly contributes to, or is only a marker of, CV risk.

In the same publication, a clear association between genetic variants for LDL levels and myocardial infarction was identified, providing further support for the causal relationship between LDL levels and CV risk.

KEY POINTS

- Monogenic disorders of lipoprotein metabolism affect structural proteins in the lipoproteins or enzymes or receptors involved in their metabolism. They can cause major physiological disruptions (e.g. steatorrhea pr pancreatitis) or be associated with dramatically increased risks of atherosclerotic cardiovascular disease. Polygenic lipid disorders are much more common and the lipid phenotypes are usually less severe than those seen in the monogenic syndromes, but can overlap the latter.

DIAGNOSIS OF LIPID DISORDERS

The diagnosis of a lipid disorder should be based on more than one measurement of serum lipids, because combined analytic and biological variations in serum lipids range from 10% to 20%. The technology for measuring LDL-cholesterol levels directly has improved steadily over the years, but in most laboratories it remains a calculated value. To perform this calculation, the total and HDL-cholesterol levels, as well as the triglyceride value, are measured. The LDL-cholesterol concentration is then estimated using a formula first devised by Friedewald et al., which has subsequently undergone several modifications by later groups. The original formula was: LDL-cholesterol = total cholesterol – [HDL-cholesterol + triglyceride/5].

The triglyceride/5 factor represents an estimate of VLDL cholesterol. The validity of this formula for estimating LDL cholesterol has been confirmed by ultracentrifugal measurement of lipoprotein levels and remains reasonably accurate as long as the total triglyceride is less than 400 mg/dL. In order to obtain an accurate calculation, patients must fast for at least 12 hours to clear their blood of any chylomicrons; these lipoproteins distort the triglyceride ratio on which the Friedewald formula relies. If the triglyceride level is greater than 400 mg/dL, the LDL cholesterol must be determined by alternative methods, although a recent report suggested a modified calculation methodology may provide better LDL-cholesterol estimation at triglyceride values above 400 mg/dL than does the Friedewald formula.[108] Apo B_{100}, which is present in both LDL and VLDL, can be measured directly to get an assessment of lower-density lipoprotein particle numbers, though this entails additional expense. With increasing evidence for a greater atherogenicity of smaller, denser LDL particles, more sophisticated assessments of LDL number and composition are being introduced into clinical practice, such as nuclear magnetic resonance spectroscopy. The place of these more sophisticated and expensive assays in the routine diagnostic evaluation of most patients remains unsettled. It appears that most patients at high risk for CHD can still be identified using traditional lower-cost laboratory assays.

Before embarking on a treatment plan in a patient with hyperlipidemia, one must exclude other medical conditions that cause lipids to rise as a secondary consequence. The most common clinical conditions that cause this to occur are obesity, diabetes, and hypothyroidism. The latter two are best screened using a serum glucose (or HbA1c) measurement and a thyrotropin-stimulating hormone level, respectively. Many medications commonly cause a secondary hyperlipidemia, with antiretroviral therapy, a variety of psychotropic drugs, estrogens, and glucocorticoids heading the list.

Increasingly, the diagnosis of severe hyperlipidemic syndromes due to rare mutations in key proteins of the lipid metabolism system can be made by genetic testing. Using buccal smears or circulating white blood cells present in a blood sample, DNA can be extracted and mutations easily detected. At the present time, these assays are typically used to guide family counseling or to provide interested patients insights into the cause of their disorder, but the results rarely affect clinical decision-making or therapeutic choices. While many of the genetic assays have moved from research tools to readily obtainable clinical tests, few are covered by medical insurance in the United States. It seems likely that the declining costs of these tests and the potential for complex genetics to offer better predictive power in assessing CV risk will shift this dynamic toward greater utility in the near future.

KEY POINTS

- Although a wide array of specialty assays for lipoprotein numbers and size are available clinically, the use of the standard lipid profile which measures the total cholesterol, HDL cholesterol, and triglyceride levels in the serum and calculates the LDL cholesterol from those numbers remains the standard for routine evaluation of a patient's lipid status.

MANAGEMENT/TREATMENT

Apart from the patient at risk for hypertriglyceridemic pancreatitis, for most hyperlipidemic patients the primary goal of treatment is to reduce the risk of atherosclerotic vascular morbidity and mortality. The approach to the treatment of hyperlipidemia that dominated clinical practice in the United States for the 25 years following the approval of the first statin in 1987 was initially delineated by the National Cholesterol Education Program (NCEP) Adult Treatment Panel I in 1988. All of the Adult Treatment Panel guidelines focused on LDL-cholesterol as the major lipid risk promoting CHD, and therapy was intended to achieve specific target LDL cholesterol levels whose selections were based on an individual's overall CV risk profile. For a given degree of LDL-cholesterol elevation, the threshold for initiation of therapy decreased and the intensity of therapy increased with increasing global CHD risk. Dietary modification, complemented by exercise and weight reduction, was to be combined with appropriate pharmacologic therapy, when needed, to achieve the targets identified in the guidelines. In the fall of 2013, a joint American College of Cardiology/American Heart Association (ACC/AHA) expert panel issued the successor guidelines to the Adult Treatment Panel series.[109] These guidelines sparked considerable controversy in the lipid field, with many dissenting voices raised over the wisdom of moving away from specific LDL targets as the goal of therapy. Others criticized the accuracy of the specific risk calculator instrument favored by these guidelines to determine if the 10-year risk was greater than or equal to 7.5%, suggesting it led to overtreatment of many individuals whose LDL-cholesterol values were less than 100 mg/dL.[110]

An update to the ACC/AHA guidelines was subsequently published.[111] The 2018 ACC/AHA Guideline on the Management of Blood Cholesterol provides evidence-based recommendations for how to safely and effectively lower LDL-cholesterol levels and improve CV outcomes.[111] The Guideline's focus is 2-fold: first, it provides recommendations for how to estimate a patient's risk of developing atherosclerotic CV disease (ASCVD). Second, it suggests courses of treatment and management based on that estimated risk. The ACC/AHA continues to recommend the use of the pooled cohort equation (PCE), which takes into account cholesterol levels as well as age, smoking history, blood pressure, and diabetes status. The ACC/AHA delineates four levels of risk based on PCE results: low (under 5%), borderline (5%–7.49%), intermediate (7.5%–19.99%), and high (20% or higher).

Both medication- and lifestyle-based treatment options exist for patients with elevated cholesterol levels. Importantly, the ACC/AHA emphasizes that PCE predictions alone should not determine whether a patient receives medications to reduce cholesterol levels. Factors including the response of a patient's cholesterol levels to behavioral changes, as well as the financial burden of the medications, should be considered as patients work with their physicians to determine the best course of treatment. Among individuals who do not have ASCVD, the ACC/AHA highlights three populations for whom medications may be appropriate to reduce LDL-cholesterol levels: individuals whose LDL-cholesterol levels are greater than or equal to 190 mg/dL, patients with diabetes, and individuals between 40 and 75 years old whose LDL-cholesterol levels are at or above 70 mg/dL and whose ASCVD risk, as calculated using the PCE, is a minimum of 7.5%. In the ladder group, calculation of a coronary artery calcium (CAC) score may help confirm the chosen course of treatment. The ACC/AHA 2018 guidelines reference studies published between 2015 and 2017 to suggest that medications may not be necessary for patients whose CAC score is equal to 0, as these patients are unlikely to develop ASCVD within 10 years. The guidelines also recommend that medications (statins) be considered for patients with CAC scores of 100 Agaston units and above, lowered from the 300 Agaston unit minimum recommended in the 2013 guidelines.[109]

Statins are recommended as the starting point of treatment for all three populations without ASCVD. Patients on "moderate" and "low-intensity" treatment regimens are expected to experience LDL-cholesterol reductions of 30% to 49% and up to 30%, respectively. Patients for whom statin treatment is infeasible at the dosage corresponding to their risk level may consider cholesterol absorption inhibitors, such as ezetimibe, or bile acid sequestrants. For patients with ASCVD, the ACC/AHA suggests "high-intensity" statin treatment, particularly for those under 75 years old. Individuals at "very high risk" may benefit from the addition of ezetimibe, known to reduce LDL-cholesterol levels approximately 18% more than statins alone, an approach with documented outcomes benefit compared with monotherapy with the same statin regimen.[112] For "very high risk" patients whose LDL-cholesterol levels remain at or above 70 mg/dL while taking statins and ezetimibe, the 2018 guidelines recommend that PCSK9 inhibitors be considered. Two recent clinical trials, FOURIER and ODYSSEY, found that the PCSK9 inhibitors evolocumab and alirocumab, respectively, can lower LDL-cholesterol levels 43% to 64% more than statins alone and can improve outcomes in individuals with preexisting CV conditions.[113,114] These data are reflected in ACC/AHA's 2018 guideline recommendations that support the use of "combination therapy" for aggressive lowering LDL-cholesterol to reduce future ASCVD events. In addition, and in contrast with the 2013 guidelines, the new guidelines recommend the use of statins at "moderate intensity" in patients who are likely to live at least 3 to 5 years who have heart failure. This recommendation stems from the results of two smaller studies on the relationship between statin administration to individuals with heart failure and CV outcomes.[115]

While medications offer one useful approach to managing cholesterol levels and ASCVD outcomes, modifications to daily dietary and exercise habits are also often effective, either on their own or in conjunction with drug treatments. A metaanalysis reported in 2018 found an association between consumption of a diet rich in plant products and a fall in LDL-cholesterol levels of approximately 17%.[116] This decrease in LDL levels corresponded with a decline of approximately 13% in the likelihood of developing CHD within 10 years. The ACC/AHA recommends intake of a vegetable-rich, sugar- and saturated fat–poor diet (for example, the Dietary Approaches to Stop Hypertension diet), as well as frequent aerobic exercise (120–160 min weekly).[109,117] Lifestyle-based approaches to managing cholesterol levels are especially important in patients under 40 years, as fewer data are available regarding CV outcomes using drug therapies in this age group. The risk-benefit calculus for utilizing preventive lipid therapies early in adulthood for individuals with average risk for CV disease is a hotly debated topic that is not informed by actual outcome data. Extrapolating benefit using genetic risk markers and short-term studies in older individuals allows one to create a compelling argument for aggressive early preventive therapy, but the realities of medication and management costs, modest drug side effects, and poor compliance with long-term preventive medications have limited the uptake of this approach in most medical practices.

KEY POINTS

- Optimum treatment of lipid disorders typically requires a combination of lifestyle approaches involving diet and activity improvements that may require adjunctive medications. Statins are the mainstay of drug treatment for those with LDL cholesterol elevations and can work well even in the patient who does not modify their lifestyle very much. Disorders of triglyceride-rich lipoproteins frequently cannot be controlled by medications alone and require comprehensive metabolic improvements to achieve normal lipid levels.

Assessing the Need to Treat Patients With Hyperlipidemia

As the magnitude of the benefit of treating hyperlipidemia is positively correlated with the overall degree of CHD risk, it is important to assess that risk before initiating treatment. Assessment should be comprehensive, extending beyond lipid levels to include consideration of blood pressure, smoking, diabetes, family history of premature CHD, age, sex, and presence of established CHD or other atherosclerotic disease. Although still in its early days, it is likely that the growing list of polygenic risk factors associated with atherosclerotic vascular disease will be incorporated into future risk-stratification schema.[103,118-121]

Treatment recommendations follow directly from the degree of estimated CHD risk. Dietary modification is the sole mode of therapy for patients at the lower end of the CHD risk spectrum, while pharmacologic measures are reserved for patients at higher risk or for those who fail dietary intervention. The trend in preventive care over the past 20 years has been to push LDL levels ever lower, with no evidence to date that a value has been reached below which no further benefit is conferred. For the highest-risk patients, the current LDL-cholesterol target is to be under 70 mg/dL, although recent outcomes studies have demonstrated LDL-cholesterol values in the 50 mg/dL range or lower are associated with improved outcomes over those of approximately 70 mg/dL.[113,114,122]

The concept that diabetes is a risk equivalent for CHD derives from the high risk of CHD in middle-aged and older diabetic populations and was exemplified in the East-West study of Finnish patients.[123] In that study, patients with prior histories of myocardial infarction and no diabetes had a 7-year incidence of new CHD events of 18.8%, whereas diabetic patients without prior myocardial infarctions had an incidence of 20.2%. The hazard ratio for death from CHD comparing these two groups did not differ. A follow-up report by the same investigators, extending to 18 years of observation and with more CHD events recorded, reaffirmed this outcome and suggested that female diabetics were at particularly high risk.[124] A finding of similar degrees of carotid intimal medial thickness in US patients with diabetes and no CHD compared with patients with CHD but no diabetes further strengthened the concept of diabetes as a CHD equivalent.[125] Several other studies in different populations have supported this conclusion.[126-130] However, not all investigations of this topic have yielded similar conclusions, with some studies indicating lower rates of future CHD events in the diabetic population without CHD than are found in nondiabetics with CHD. Other studies have indicated that gender substantially influences this comparative outcome.[131-138] What all studies demonstrate, however, is that diabetes does confer a substantial increase in CHD risk, and that the combination of diabetes and CHD puts individuals at a very high risk of a future coronary event. Treating diabetes as a CHD risk equivalent in middle-aged and older patients does, therefore, appear to be clinically appropriate.

Other commonly assessed risk factors not included in most guideline calculations of risk include obesity, impaired fasting glucose, markers of inflammation (e.g., high sensitivity C-reactive protein), homocysteine, endothelial dysfunction, and a thrombosis predilection. The role of these other risk factors in improving prognosis remains controversial, but clinicians may want to modulate the standard risk-factor treatment guideline based on the presence or absence of these nontraditional risks in their individual patients.

Dietary and Drug Treatment of Lipid Disorders

Diet/Lifestyle Therapies. With the advent of very potent lipid-lowering therapies, the use of dietary approaches to controlling lipid levels has become deemphasized in much of the developed world. While drug treatments (especially for elevated LDL-cholesterol levels) are very effective, the role of diet in promoting hyperlipidemia should not be forgotten. The dietary approach to the treatment of elevated LDL-cholesterol levels focuses on reductions in saturated fat, partially hydrogenated unsaturated fatty acids, and dietary cholesterol. Substituting foods that provide polyunsaturated and monounsaturated fats in place of saturated and *trans* unsaturated fat is particularly important, whereas the value of reducing the total fat intake is less clear.[139] The 2013 clinical practice guidelines of the American Diabetes Association (ADA) recommend that saturated fat intake be restricted to less than 7% of calories, and that cholesterol intake not exceed 200 mg per day in patients with diabetes. These dietary recommendations mimic those proposed by the NCEP Adult Treatment Panel III guidelines for individuals without diabetes who have established coronary disease. For nondiabetics without coronary disease, the NCEP liberalizes saturated fat intake to less than 10% of calories and cholesterol to less than 300 mg/d. In both diets, it is recommended that *trans* fat intake be kept to a minimum. The adoption of a Mediterranean-style diet, with substitution of monounsaturated fats for saturated fat, has demonstrated benefits on LDL cholesterol reduction, insulin sensitivity, and endothelial reactivity.[11,140,141] The magnitude of the LDL reduction achieved with dietary interventions is quite variable and depends on the preintervention diet, as well as metabolic and genetic factors that influence diet-dependent lipid responses. LDL reductions of 5% to 20% are typical for most patients adopting the reduced fat and cholesterol diets recommended by the ADA and NCEP, but reductions of over 50% can occur in selected individuals.[142]

For patients with VLDL elevations, which include a large portion of the diabetic population, carbohydrate and alcohol consumption may be more important dietary factors to address than the intake of cholesterol or saturated fat. The current United States Department of Agriculture–recommended daily allowance of carbohydrate is 130 g/d, but studies of long-term carbohydrate-restricted diets are limited. Recently, investigations comparing low-carbohydrate and low-fat diets have demonstrated that low-carbohydrate diets can produce as good or even modestly better weight reduction than can low-fat diets in 6- to 12-month timeframes.[143-145] The lower-carbohydrate, higher-fat diets typically produce greater reductions in VLDL (serum triglycerides) and greater increases in HDL-cholesterol than do the fat-restricted, higher-carbohydrate diets. On the low-carbohydrate, higher-fat diets, the LDL-cholesterol level can vary significantly, and if a substantial amount of saturated fat is used in these diets, the rise in LDL could be substantial.[146] Therefore, the use of low-carbohydrate diets should be accompanied by the use of monounsaturated and polyunsaturated fats as the major sources of fat in the diet.

Weight loss (if obese), aerobic exercise, and smoking cessation can increase HDL levels and contribute to the dietary lowering of lower-density lipoproteins and CHD risk. They also reduce CHD risk by decreasing blood pressure. In the Diabetes Prevention Program (DPP), subjects in the lifestyle intervention group reduced their fat intake to 28% of calories after 1 year (down from 34%), and most were able to maintain the goal of 150 minutes per week of moderate physical activity.[147,148] On this program, in which a body weight loss of 7% was targeted, subjects experienced less progression to diabetes and reductions in multiple CV risk factors, including dyslipidemia and hypertension.[149,150] Although the DPP was conducted in an academic environment with substantial investigative resources devoted to ensuring compliance with the program, more recent efforts modeled on DPP suggest that the results can be translated to community-based outreach programs.[151,152]

The clinical trials data that demonstrate improvements in CAD outcomes as a result of dietary interventions alone have generally employed diets that restrict fat and/or cholesterol intake much more dramatically than the ADA and NCEP diets mentioned earlier. In the St. Thomas' Atherosclerosis Regression Study (STARS), cholesterol intake in men was reduced to 100 to 120 mg/d, and excess weight was addressed by prescribing a physical activity program. After 3 years, the group treated with a low-cholesterol diet had a slower rate of progression of coronary disease and a higher rate of regression as determined by angiography.[153] The Lifestyle Heart Trial employed an even more stringent diet, reducing cholesterol intake to less than 10 mg/d, combined with an exercise and behavioral modification program. This intervention led to regression of coronary lesions as measured by angiography and a reduction in symptoms of ischemia.[154] This study was conducted in a very small number of highly motivated volunteers; it would be challenging to replicate the same interventions in more typical clinical care settings. Nevertheless, a longer-term follow-up of a small number of participants in this study demonstrated that further regression of coronary atherosclerosis could be obtained.[155] A study with potentially greater applicability than either STARS or the Lifestyle Heart Trial is the Lyon Diet Heart Study.[156-158] Conducted using a Mediterranean diet rich in alpha-linolenic acid, with participants who had experienced a prior myocardial infarction, this trial demonstrated improvements in its primary endpoint (myocardial infarction and death) as well as several CV and secondary endpoints. These results have been validated in the Spanish PREDIMED study of 7447 individuals with either type 2 diabetes mellitus or at least three major CV risk factors who were randomized to a Mediterranean or control diet.[159] Participants in the Mediterranean diet groups experienced a 30% relative reduction in CV events, which was driven by a decrease in stroke rates. The Lyon Diet Heart Study and PREDIMED results, combined with other investigations of the impact of similar diets on lipids and lipoproteins, provide substantial support for the utility of Mediterranean-style diets in the prevention and treatment of CHD.

Outcome Studies of Pharmacologic Therapy for Hyperlipidemia

The addition of drug therapy to a diet and exercise program can greatly enhance lipid-lowering results and dramatically effect CHD outcomes. Numerous investigations over the past 30 years have demonstrated that the use of one class of drugs, the HMG CoA reductase inhibitors, or statins, leads to significant reductions in nonfatal and fatal cardiac events (i.e., myocardial infarction, revascularization, cardiac death) in appropriately selected populations. Reductions in all-cause mortality have also been demonstrated in lipid-lowering drug trials, particularly in higher-risk populations. With intensive drug therapy, the rate of plaque progression falls, and modest plaque regression can be demonstrated in major coronary vessels and systemic arteries. There is also evidence that lipid-lowering medication (statins) can reduce the risk of stroke in persons with atherosclerotic carotid disease. These benefits have been shown to accrue to men and women, diabetics and nondiabetics, and middle-aged and older individuals. A summary of the major outcomes studies using statins is provided in the coming paragraphs, followed by a brief review of the data available for outcomes using drugs that are not HMG CoA reductase inhibitors.

KEY POINTS

- The value of lipid-lowering in improving cardiovascular outcomes has been one of medicine's most intensely investigated topics. Statins and other more recently approved LDL cholesterol lowering drugs, when given to patients with clinically documented ASCVD and elevated LDL cholesterol levels, have proven benefits. For those with lower risks for future ASCVD events the benefit of preventive lipid therapy is not as great in the short-term but may still be valuable over longer timeframes.

Coronary Heart Disease Outcomes with 3-Hydroxy-3-Methylglutaryl Coenzyme A Reductase Inhibitors (Statins).

The current era of lipid-lowering therapy began in 1984 with the publication of the Lipid Research Clinics Coronary Prevention Trial. A randomized, double-blind study employing cholestyramine compared with placebo, this trial demonstrated that an 8% reduction in total cholesterol yielded a 19% reduction in CHD death or myocardial infarction.[160,161] With the advent of statin therapy in 1987, much more effective LDL-cholesterol–lowering agents became available. During the 1990s, a series of landmark CV prevention trials were completed using these agents. In 1994, the Scandinavian Simvastatin Survival Study (4S) established for the first time that a lipid-lowering agent could prolong overall survival in individuals with preexisting CHD.[162] Randomizing 4444 patients with a prior myocardial infarction or angina to simvastatin or placebo, the drug treatment cohort of 4S had baseline LDL-cholesterol levels fall from approximately 190 mg/dL to 120 mg/dL. With a trial endpoint of death for 10% of the original study enrollees (444 study subjects), it took a little over 5 years to complete the study. The result was that 8% of the simvastatin patients died versus 12% of the placebo-treated individuals. This 30% reduction in mortality established statin therapy as an essential intervention in CHD patients with significant LDL elevations. In addition to the mortality benefit, 4S also produced substantial reductions in major coronary events, overall CHD death (19% vs. 28%, a relative risk reduction of 42%), and cerebrovascular events (2.7% vs. 4.3%). Unlike several of the pre–statin era cholesterol intervention studies, there were no increases in other causes of mortality to counterbalance the benefits on the CV system. When 4S was examined in greater detail, and after longer follow-up to determine if the therapy had been confined to any subset of patients, these analyses concluded that the benefit was widespread.[163-165] Individuals at the highest risk appeared to benefit the most, particularly those with diabetes.[166] Though only 202 of the 4444 patients in 4S were diagnosed with diabetes, these individuals experienced relative risk reductions in mortality (43%) and major CHD events (55%) that exceeded those in the nondiabetic population. An equally impressive outcome was noted in individuals who, in addition to their elevated LDL-cholesterol levels, had lipid phenotypes characteristic of the metabolic syndrome (low HDL-cholesterol levels and high triglycerides). Study subjects with this lipid triad had the highest event rates among those receiving placebo (35.9%) and the greatest reduction in relative risk with treatment (0.48; 95% CI: 0.33–0.69).[167]

Subsequent studies have further refined our understanding of the benefits of statins in patients with and without preexisting CHD. The West of Scotland Coronary Prevention Group study (WESCOPS) enrolled hyperlipidemic men who had not experienced a prior myocardial infarct but who had high levels of other CHD risk factors. Pravastatin reduced LDL-cholesterol levels from approximately 190 mg/dL to 140 mg/dL and, compared with the placebo-treated group, lowered CHD death and myocardial infarction by 30%.[168]

An improvement of similar magnitude in a younger population of lower-risk patients was observed in the Air Force/Texas Coronary Atherosclerosis Prevention Study when lovastatin was given to men and women with starting LDL-cholesterol levels of 150 mg/dL.[169] When compared with the placebo-treated patients, those receiving lovastatin reduced their LDL on average to 115 mg/dL and decreased their incidence of major coronary events by 30% to 40%. In the Cholesterol and Recurrent Events Trial (CARE), pravastatin was given to patients with myocardial infarctions whose LDL-cholesterol levels were substantially below (mean of 139 mg/dL) those of the 4S and WESCOPS patients. With a primary endpoint of a fatal coronary event or a nonfatal myocardial infarction, the pravastatin-treated group had a 24% relative risk reduction compared with placebo-treated patients. Stroke was reduced 31%.[170] A *post hoc* analysis of CARE by the investigators who performed it led to the conclusion that reduction of LDL-cholesterol in the range from 174 mg/dL to 125 mg/dL lowered the coronary event rate, but that further reductions below 125 mg/dL did not appear to confer additional benefit.[171] The value of LDL reductions to levels substantially below 125 mg/dL has been a topic of considerable controversy ever since CARE was published, but several subsequent studies have indicated that further reductions of LDL do confer benefit. For example, the Long-Term Intervention with Pravastatin in Ischaemic

Disease study group enrolled over 9000 patients with recent evidence of CHD and demonstrated benefits in overall mortality and CHD death using pravastatin.[172] When stratified by starting LDL-cholesterol, the magnitude of the benefit appeared to be maintained even in those with starting levels below 116 mg/dL.[173-175] The Treating to New Targets trial enrolled 10,000 patients with stable CHD and randomized treatment to high-dose (80 mg/d) or low-dose (10 mg/d) atorvastatin.[176] Pretreatment LDL-cholesterol levels were between 130 mg/dL and 250 mg/dL, and posttreatment LDL-cholesterol values were 77 mg/dL and 101 mg/dL, respectively, in the high- and low-dose groups. The primary endpoint of the study, which was major CV events, declined 22% more in the high-dose group than the low-dose cohort, as did rates of myocardial infarction and stroke. However, overall mortality was not lower in the high-dose group, owing to an increase in non-CV deaths. Cancer deaths accounted for most of these events, a finding not replicated in other studies using the same drug.

The Heart Protection Study (HPS), like several of its predecessor trials, attempted to examine the question of LDL-cholesterol lowering in patients with moderate hyperlipidemia. HPS was a much bigger trial, randomizing 20,536 patients to placebo or simvastatin (up to 40 mg/d). The inclusion criteria required evidence of prior CV disease and permitted a broad range of LDL-cholesterol levels, with a third of the patients having values less than 116 mg/dL. After an average follow-up of 5.5 years, all-cause mortality was reduced in the statin-treated cohort, as was CHD death and major CV events.[177] Notably, over 5000 diabetics were included in the study, and they also achieved a substantial relative risk reduction in myocardial infarction and stroke.[178,179] Particularly striking was the finding that the benefits of LDL-cholesterol lowering were produced in all three of the tertiles into which patients' baseline LDL-cholesterol were stratified. Even those with starting LDL-cholesterol levels approximating the current NCEP target goal of 100 mg/dL (for those with CHD) had a benefit when their value was reduced substantially below that number. Both men and women, as well as older and younger patients, derived similar benefits from the statin treatment. As with HPS, the Collaborative Atorvastatin Diabetes Study demonstrated a significant benefit in diabetic patients with lower LDL-cholesterol levels (<160 mg/dL) randomized to the statin arm of a placebo-controlled trial.[180] This benefit appeared in those whose starting LDL-cholesterol levels were both above and below 120 mg/dL. After 4 years of follow-up, the rate of CV events dropped 37% (95% CI: –52% to –17%).

The JUPITER study attempted to answer whether LDL lowering with rosuvastatin was beneficial for healthy individuals whose LDL levels were considered normal but who had elevated C-reactive protein (CRP) levels.[181] Over 17,000 men and women with LDL less than 130 mg/dL and high-sensitivity CRP values of 2.0 mg/L or higher were randomized to rosuvastatin 20 mg daily or placebo and followed for CV events. The trial was stopped after 1.9 years; at that time, LDL levels were reduced by 50% (to 55 mg/dL), high-sensitivity CRP levels by 37%, and CV events by 44% in the rosuvastatin group. This study supported the hypothesis that LDL lowering below the targets recommended at that time could be beneficial for a subset of apparently healthy individuals who have evidence of atheroinflammation, as indicated by the high-sensitivity CRP assay. In addition to studies of their effects on major clinical outcomes, many of the statins have been used in trials assessing their effects on atherosclerosis progression or regression in the coronary arteries or the carotids. The Familial Atherosclerosis Treatment Study compared three regimens that all contained a bile acid resin binder, colestipol, plus placebo, niacin, or lovastatin. The lovastatin-treated cohort lowered its LDL by 46% and had more regression and less progression of their CAD, as assessed by angiography, than did the placebo-treated group. The niacin group's response was equivalent to that seen with the lovastatin treatment.[182] The Regression Growth Evaluation Statin Study utilized pravastatin in over 800 men with total cholesterol levels between 155 mg/dL and 310 mg/dL to demonstrate delayed progression in CHD, as well as a lower rate of progression of femoral and carotid atherosclerosis.[183,184] The REVERSAL trial compared atorvastatin (80 mg/d) to pravastatin (40 mg/d) in patients with CHD by assessing plaque volume using intravascular ultrasound measurements (IVUS). Atheroma volume declined slightly in the atorvastatin-treated group, while increasing in the pravastatin cohort, and the difference between the two was statistically significant.[185] ASTEROID employed an open-label treatment with rosuvastatin (40 mg/d) in 507 patients with CHD to lower LDL-cholesterol by 53% (from a mean of 130 mg/dL to 61 mg/dL). With this intervention, atheroma volume, as measured by IVUS, was reduced. No control group was included in ASTEROID, making it difficult to assess what is otherwise an impressive reduction in coronary atherosclerosis.[186] Taken together, these statin studies provide impressive evidence that aggressive lipid lowering can reduce the rate of CAD progression in patients with established disease and may, with the most intensive therapy, even cause plaque regression.

In addition to their use in studies of patients with longstanding stable CHD, statins have been employed in the setting of acute or recent coronary syndromes to determine if more aggressive lipid lowering might provide additional benefit in these settings. The Prove-It study, for example, compared individuals with starting LDL-cholesterol levels of approximately 110 mg/dL who were randomized to receive pravastatin (40 mg/d) or atorvastatin (80 mg/d) after an acute coronary event.[112] The high-dose atorvastatin group lowered LDL-cholesterol levels to 62 mg/dL, whereas the middose pravastatin cohort only reduced their LDL-cholesterol values to 95 mg/dL. A 16% reduction in coronary events was achieved on the more aggressive therapy. It seems probable that this study established that an LDL-cholesterol of 62 mg/dL is better than one of 95 mg/dL in patients experiencing an acute coronary event, but the more rigorous conclusion is that 80 mg of atorvastatin works better for CHD outcomes in this population than does 40 mg of pravastatin. Similarly, the Incremental Decrease in End Points through Aggressive Lipid-lowering study used an open-label/blinded-endpoint study design to randomize nearly 9000 patients with a past history of myocardial infarction to receive either atorvastatin (80 mg/d) or simvastatin (20 mg/d).[187] After 24 weeks, the dose of simvastatin could be raised to 40 mg/d if the LDL-cholesterol remained greater than 190 mg/dL. The atorvastatin-treated cohort after nearly 5 years had a mean LDL-cholesterol that was lower than the simvastatin-treated cohort (81 mg/dL vs. 104 mg/dL), but no significant reduction in the primary endpoint of major coronary events was demonstrated. While there were reductions in some secondary endpoints on atorvastatin, no benefit on overall mortality was seen. Because several of the above studies employed different drugs and achieved different LDL endpoints using those agents, it is not always easy to interpret the outcomes. Overall, the data do support aggressive lipid-lowering therapy in the acute coronary setting, but it is much less clear whether one drug is superior to another when nearly comparable LDL-cholesterol lowering is achieved.

In summary, the outcomes studies presented in this section demonstrate that LDL-cholesterol reduction with multiple members of the statin class of drugs results in improvements in CHD events and in overall total mortality in patients with established coronary disease. These benefits are present or even magnified in individuals with diabetes or the metabolic syndrome. Lower rates of CHD events are also produced in patients without established CHD but who have substantial

CHD risk factors. In lower-risk populations, statins clearly reduce coronary events, but data are less convincing for benefits on CHD death or overall mortality. These conclusions have been confirmed by several metaanalyses of clinical trials that employed a variety of statins.[188-190] Although the precise goal of LDL-cholesterol reduction remains controversial, the NCEP guideline targets of progressively lower target LDLs for progressively higher levels of risk (i.e., <130, <100, and <70 mg/dL) are both reasonable and consistent with the findings of outcomes studies published to date.

Concerns about cholesterol-lowering producing increased risks of cancer and violent deaths, which emerged in some of the early, prestatin lipid-lowering trials, have largely been put to rest in the major prospective statin studies. In studies of over 25 randomized control trials, including five of the largest such trials conducted to date (using several different members of the statin class of drugs and collectively involving ~90,000–175,00 patients), no increase in the rates of cancer or noncardiac deaths have been reproducibly observed.[191,192] However, each class of cholesterol-lowering drug therapies has important adverse effects that need to be taken into account when considering pharmacologic intervention. With the trend towards more aggressive lowering of LDL-cholesterol, achieved through higher doses of statins and more complex multidrug regimens, comes an increase in the risk of drug side effects.

Another concern that has emerged recently pertains to the effect of statins on diabetes incidence. In addition to demonstrating clear evidence for CV benefit from LDL reduction, the JUPITER trial provided evidence for a 25% increase in new physician-diagnosed diabetes during statin treatment.[181] Following the publication of the JUPITER trial, two metaanalyses of large, placebo-controlled trials were rapidly performed.[193,194] Both of these studies reported a small but consistent increase in diabetes incidence (9%–13%) during statin treatment. These findings suggest that treating 255 patients with statins for 4 years would result in one additional case of diabetes. Although not directly comparable, a prior metaanalysis had concluded that five myocardial infarctions could be prevented for every case of diabetes occurred.[195] Thus, based on the present data, the benefits of statin therapy appear to clearly outweigh the small risk of increased diabetes incidence.

Whether statin therapy should be initiated in young individuals is a topic of debate, with little data available to inform the discussion. Young men (aged less than 35 years) and premenopausal women with no CHD risk factors other than hypercholesterolemia are typically at very low 10-year risks for developing CHD. An argument can be made to wait until the risk level escalates before initiating cholesterol-lowering therapies, inasmuch as the benefits of statin therapy are typically evident in less than 2 to 3 years. An alternative view cites the evidence that individuals with genetically-driven low LDL-cholesterol levels have extremely low rates of CHD, and that one should try to mimic this lifelong low-cholesterol state with earlier and more aggressive drug therapy.[88] Both perspectives have merit. For now, making a decision on intervention in younger patients will likely balance the magnitude of the individual risk with preferences for more or less aggressive therapy on the part of both physician and patient. Physicians prescribing statins for young women, however, must not forget the potential teratogenicity of this class of drugs, which remains contraindicated in pregnancy. Nonpharmacologic therapy, primarily focusing on improved diets and physical activity programs, should be adopted regardless of age. As widespread clinic use of statins moves into its fourth decade and the initially approved agents have become available in generic forms, the safety and cost issues associated with their use may recede in importance, and a greater consensus on earlier use of these remarkable drugs becomes possible. For now, the exercise of good clinical judgment is essential in these circumstances.

Proprotein Convertase Subtilisin Kexin 9 Inhibitors and Cardiovascular Benefit. The most effective LDL-lowering agents for patients who are either unable to achieve target LDL goals on statins or who are unable to tolerate statin use at all are the monoclonal antibody therapies directed against PCSK9, alirocumab and evolocumab. Preapproval studies showed excellent lipid-lowering efficacy as monotherapy and in combination with statins.[196-204] Evolocumab was found to lower LDL-cholesterol levels by 59% and the incidence of myocardial infarction, stroke, and coronary revascularization by 21% to 27% in a 20,564-participant clinical trial called FOURIER.[113] All study participants had been diagnosed previously with ASCVD and had LDL-cholesterol levels above guideline targets despite statin treatment. ODYSSEY, an 18,924-participant study investigating the use of alirocumab in patients with a history of recent acute coronary syndrome who were unable to achieve optimum LDL-cholesterol levels on statins, demonstrated an LDL-cholesterol reduction of approximately 55% to 60%. This reduction led to a significant benefit on a composite of CV outcomes, as well as a modest overall mortality benefit.[114]

Cardiovascular Outcomes Trials With Agents Other Than Statins and Proprotein Convertase Subtilisin Kexin 9 Inhibitors. As cited in the previous section, the current era of lipid lowering was successfully initiated with a bile acid resin binder, cholestyramine.[160,161] Though achieving an LDL-cholesterol reduction of only 8%, CHD events were reduced 19%. Thus, it is the belief of most experts in the lipid field that LDL-cholesterol lowering achieved by virtually any means will result in reduced CHD events, provided the therapeutic approach does not have off-target consequences that would countervail the benefit of the LDL lowering. This view is supported by a wealth of data on the pathogenesis of atherosclerosis, as well as clinical trials of multiple modalities that lower LDL-cholesterol, including nonpharmacologic approaches.[155,205-208] At the current time, statin use supersedes that of all other LDL-cholesterol–lowering agents as first-line monotherapy because of outstanding efficacy, low cost, and the wealth of outcomes data establishing its benefit. Many patients, however, either cannot meet the LDL targets set by guidelines or cannot achieve the levels obtained in the major outcomes trials using statins alone. Some patients have inadequate therapeutic responses to the drugs, while others cannot tolerate their adverse side effects. When that occurs, the use of other lipid-lowering agents becomes relevant. If the patient has documented ASCVD, PCSK9 antibodies can usually be added or used instead of statins, though cost remains a barrier to that approach for many patients due to drug insurance gaps or expensive copay payments. The following section addresses the current data on outcomes when therapeutics other than statins or PCSK9 inhibitors need to be considered.

Fibrates and Coronary Heart Disease Outcomes. Unlike statin therapy, none of the other oral LDL-cholesterol–lowering medications have produced an overall mortality benefit in a randomized, prospective, double-blind trial. For the most part, this is because studies employing those agents were not powered for a primary outcome focused on mortality, but instead targeted reductions in CHD events. With the latter endpoint, bile acid resins, gemfibrozil, and niacin have all been demonstrated in long-term prospective studies to reduce CHD and/or major CV events.[160,161,209-213] Although not available in the United States, bezafibrate also showed promising results in a secondary prevention study.[214] Because fibrates (gemfibrozil, fenofibrate, bezafibrate, clofibrate, and ciprofibrate) are more effective than statins at lowering serum triglyceride/VLDL levels, they would appear to be particularly attractive agents for the treatment of the dyslipidemia associated with diabetes and the metabolic syndrome. Subgroup analyses of many studies employing fibrates support this hypothesis, with greater benefit shown in those with high triglycerides and low HDL.[215] Insofar as neither bezafibrate nor ciprofibrate are available in the United States, and clofibrate is no longer used because of a significantly higher mortality rate due to non-CV adverse events produced by the drug, these agents will not be discussed in this section.

Of the fibrates, then, only fenofibrate and gemfibrozil are prescribed in the United States. Gemfibrozil was used in two major trials, the Helsinki Heart Study (HHS) and the Veterans Affairs High-Density Lipoprotein Intervention Trial (VA-HIT), with both reporting substantial benefit from the drug. The HHS was a double-blind, placebo-controlled 5-year trial that targeted HDL-cholesterol–raising and non–HDL-cholesterol–lowering.[209] A group of 4081 asymptomatic men with non-HDL-cholesterol levels greater than 200 mg/dL were studied over a 5-year period, with approximately half receiving 600 mg twice daily of the fibrate and half on placebo. HDL-cholesterol, non–HDL-cholesterol, LDL-cholesterol, and triglycerides all improved in the drug-treated cohort, which experienced a 34% reduction in CHD events. On drug treatment, HDL-cholesterol rose 11%, LDL-cholesterol fell 10%, and triglycerides dropped 35%. Subsequent subgroup analysis of this study showed that the greatest benefits were achieved in those with body mass indexes above 26 kg/m^2 or in individuals who had higher triglyceride levels or lower HDL-cholesterol values.[216] In the VA-HIT study, 2531 men with established CHD, LDL-cholesterol levels less than or equal to 140 mg/dL and HDL-cholesterol levels less than 40 mg/dL were treated with gemfibrozil (1200 mg/d) or placebo.[210] Those who received the fibrate experienced a 22% reduction in the primary outcome of nonfatal myocardial infarction or CHD death. These benefits were associated with a 6% higher HDL-cholesterol level, a 31% lower serum triglyceride value, and no significant change in LDL-cholesterol. Subgroup analysis in this study again revealed that those benefiting the most from the drug were individuals whose HDL-cholesterol rose. Somewhat surprisingly, the improvement in triglyceride was not associated with an improved CHD outcome.[217] The serious adverse events seen with clofibrate were not reproduced in the gemfibrozil studies, though overall mortality benefits were also not demonstrated in either study.

The results of the HHS and VA-HIT studies convinced many lipid experts that fibrate treatment was beneficial, and these agents were widely prescribed from 1990 to 2010 to treat hypertriglyceridemia and low HDL-cholesterol levels. As gemfibrozil was found to affect the metabolism of multiple statins, many lipid experts switched to using fenofibrate whenever a statin/fibrate combination therapy was deemed appropriate in order to reduce the likelihood of a serious myopathy.[218] Thus, the publication of the Fenofibrate Intervention and Event Lowering in Diabetes Study (FIELD) in 2005 was a much-anticipated event in defining lipid therapeutics.[219] This trial randomized 9795 middle-aged and older patients with type 2 diabetes to placebo or micronized fenofibrate (200 mg/d). Patients qualified by having total cholesterol levels between 116 mg/dL and 252 mg/dL and total/HDL-cholesterol ratios greater than 4.0 or plasma triglycerides between 88 mg/dL and 435 mg/dL. An unusual feature of the FIELD trial was that patients were permitted to be treated with other lipid-lowering agents at their own physician's discretion, so many received simultaneous statin therapy. The primary outcome of the study was CHD events. Triglycerides were reduced by the fibrate by 29%, but HDL-cholesterol rose by only 2%. While CHD events were reduced in the drug-treated group by 11%, this overall outcome was not statistically significant. More worrisome was the fact that the overall event rate represented the average of a positive and negative outcome, with nonfatal myocardial infarction falling 24%, but CHD mortality rising by 19%. When total mortality was examined, it was not significantly higher in the fenofibrate cohort. Overall, the FIELD study was widely perceived to have failed to deliver the expected benefits suggested by the earlier gemfibrozil studies. This outcome has led to vigorous and protracted debates about the utility of fibrate therapy in general, and fenofibrate in particular.

The Action to Control Cardiovascular Risk in Diabetes trial was designed to investigate fenofibrate's value in a diabetic population, randomizing 5518 patients with type 2 diabetes to placebo or fenofibrate.[220] All patients were also receiving simvastatin as background therapy. In patients receiving fenofibrate, triglycerides were reduced by 14%, and HDL increased by 2%. However, LDL levels were unaffected by fibrate therapy, and total mortality and the primary endpoint of CV events were similar in the placebo and fenofibrate groups. Despite the epidemiologic evidence linking high serum triglycerides to CHD events, the data from fibrate intervention studies have not consistently shown that reductions in triglycerides result in CHD benefit. As pointed out earlier in VA-HIT, the effect on HDL-cholesterol levels, though modest, correlated with the desirable CHD outcomes, while the marked triglyceride reduction of 31% did not. Thus, the triglyceride-lowering effect of fibrates may be most clinically valuable when treating severely hypertriglyceridemic patients (serum triglycerides >500 mg/dL) in whom the goal is to prevent triglyceride-induced pancreatitis. Future studies with fibrates may clarify their place in the prevention of CHD, but at present the currently available agents do not appear to have a great enough therapeutic benefit in most CHD patients to warrant widespread use.

Other Classes of Drugs to Treat Hyperlipidemia. Three other classes of drugs are commonly used to treat patients with hyperlipidemia: (1) nicotinic acid or niacin, (2) cholesterol absorption inhibitors (bile acid resins and ezetimibe), and (3) omega-3 fatty acids or fish oils. The decrease in CHD produced with niacin in the Coronary Drug Project, combined with long-term follow-up of those originally assigned the drug, provide substantial confidence in the therapeutic value of using this B vitamin.[212,221] While there is evidence for benefit when niacin is combined with a statin,[222,223] the AIM-HIGH study raised new questions about which patients are likely to obtain a benefit from niacin.[224] In AIM-HIGH, 3414 patients with CV disease who were already on statin therapy were randomized to niacin or placebo. The niacin arm failed to show a benefit of the drug on CV event rates despite raising HDL-cholesterol and lowering triglycerides and LDL-cholesterol levels substantially better than the placebo treatment. It is important to remember, however, that niacin was being added to a regimen that had already reduced LDL-cholesterol levels to approximately 70 mg/dL, so the lack of efficacy in this group may not be relevant to populations whose pretreatment LDL values are substantially higher. Niacin can lower triglycerides, raise HDL-cholesterol, and reduce LDL-cholesterol, so it can provide a very useful adjunct to statin therapy in treating patients with combined lipid disorders. Its side-effect profile and its potential for increasing insulin resistance are the major drawbacks to employing niacin more widely.

Bile acid resins were the mainstays of lipid therapy prior to the advent of statins; multiple CHD outcomes and atherosclerosis progression studies were performed with various members of the class. Overall, despite only modest LDL-cholesterol–lowering performance, these drugs yielded benefits on CHD and coronary atherosclerosis when given as monotherapy or in combination with niacin or sta tins.[153,160,161,182,225] Because bile acid resins can interfere with the absorption of other drugs, cause substantial gastrointestinal bloating and constipation, and often substantially increase serum triglycerides, the development of much more selective cholesterol absorption inhibitors was highly desirable. Ezetimibe, which inhibits cholesterol absorption from the gut via blockage of enterocyte cholesterol trafficking pathways, rapidly replaced bile acid resins in the lipid-therapeutic armamentarium because of its ease of use. In its first major outcome study, the addition of ezetimibe to simvastatin provided no additional benefit beyond simvastatin alone on carotid intimal medical thickness assessed by carotid sonography.[226] This controversial study demonstrated substantial additional LDL-cholesterol reduction with ezetimibe (16.5% greater than the simvastatin alone), indicating that the drug was effective in its primary action in the cohort that received it. The short duration of treatment, the mild degree of carotid disease at the outset of the study, and the use of patients previously treated with statins for many years may have all combined to make it extremely challenging for this study to have shown a benefit. Subsequently, the IMPROVE-IT trial showed that the combination of simvastatin (40 mg) and ezetimibe (10 mg) reduced LDL-cholesterol further than the simvastatin alone and lowered CV events.[122] This trial provided evidence that lowering LDL-cholesterol, even with a nonstatin medication, can lead to a reduction in CV events.

Another major category of hypolipidemic agents, omega-3 fatty acids, is moderately effective in lowering elevated serum triglycerides. At doses of 2 to 4 g/d, omega-3 fatty acids inhibit VLDL production, while having little or no effect on HDL-cholesterol. In hypertriglyceridemic subjects, there is typically a small rise in LDL-cholesterol when omega-3 preparations are used that contain both EPA (eicospentanoic acid) and DHA (docosahexaenoic acid). While there are many epidemiologic studies of fish consumption that suggest that fish oils produce a CV benefit, demonstrating that benefit in prospective trials of fish oil supplements has been difficult. Three large CV outcome studies were performed in the past decade testing the efficacy of fish oils.[227-229] These studies used differing amounts of the omega-3 fatty acids in different subsets of patients with varying degrees of CV risk, including patients with a history of prior myocardial infarction or diabetes. In all three studies, triglycerides were reduced, but none of the populations obtained a CV benefit from the tested preparations. The best available evidence suggested that omega-3 fatty acids may reduce lethal cardiac arrhythmic events but have a modest effect, if any, on coronary atherosclerosis.[230-232] Newer, EPA-only fish oil formulations appear to have a more favorable impact on LDL-cholesterol levels than preparations containing DHA, although this impact is usually lesser LDL-cholesterol elevation, not actual LDL-cholesterol lowering.[233] The REDUCE-IT trial compared icosapent ethyl 2 g twice daily to placebo in 8179 patients with CV disease (or who were 50 years old and had diabetes mellitus and at least one additional CV risk factor). Patients in the trial had fasting triglyceride levels between 135 mg/dL and 499 mg/dL, and almost all were receiving statin therapy. In contrast with other fish oil intervention trials utilizing combination fish oil formulations, REDUCE-IT demonstrated a statistically significant 25% reduction in the primary composite CV outcome.[234] The results of this study have been widely debated due to its benefits where other fish oil trials proved ineffective and because the mechanism through which the benefit was conferred remains uncertain. Again, as with the fibrate studies, the lowering of triglyceride levels did not appear to correlate well with the CV outcome benefit. Although there were higher rates of atrial fibrillation in the patients receiving the fish oil, as well as a modest and statistically nonsignificant increase in serious bleeding events, isocapent ethyl has become, as a result of the REDUCE-IT trial, the clearly preferred fish oil agent when used for the purpose of producing a CV outcome benefit.

Future Therapies. Several newer agents have been studied in the past few years that may prove useful in the near future for the treatment of lipoprotein disorders.

Bempedoic acid: This drug is an oral inhibitor of ATP citrate lyase, an enzyme linked to the cholesterol synthesis pathway, that reduces LDL-cholesterol. In a trial of 2230 patients on maximally tolerated statins whose LDL-cholesterol levels remained above 70 mg/dL, bempedoic acid was shown to reduce LDL values by approximately 18% compared with those measured in the group receiving placebo treatment. The drug did produce more gout adverse events. A greater incidence of tendon rupture has also been reported. In February 2020, the FDA approved this drug for use in adult FH heterozygotes or individuals with established ASCVD who require more LDL-cholesterol lowering. Its place in therapeutic algorithms is still uncertain, but clearly it would be utilized only if statin and/or ezetimibe therapy were unable to meet lipid-lowering goals.[235]

Inclisiran: This small interfering RNA molecule is a PCSK9 inhibitor that works via inhibition of the production of PCSK9 protein rather than by binding the secreted protein, as the antibodies alirocumab and evolocumab do. In the ORION study, 482 adults with heterozygous FH on maximal tolerated statin therapy were given subcutaneous injections of the inclisiran on days 1, 90, 279, and 450. At day 510, inclisiran reduced baseline LDL-cholesterol values of 153 mg/dL by a placebo-adjusted approximately 48%.[236] Inclisiran was approved in Europe in December 2020, but has not yet received approval in the United States. The twice-a-year dosing regimen of the drug could improve patient compliance with lipid medications, and, if priced substantially below the cost of the PCSK9 antibodies, it may provide greater access to this pathway for LDL-cholesterol lowering.

Antisense Rx of Lp(a): Another antisense therapy called AKCEA-APO(a)-LRx has demonstrated very significant reductions in lipoprotein(a) (also called Lp(a)). This lipoprotein represents a covalent linkage between a protein called apoprotein(a) and an LDL molecule. Higher levels of Lp(a) are positively correlated with higher ASCVD risk and are primarily determined by the genetic isoforms of apolipoprotein that a patient carries. No current therapy for lowering Lp(a) has been approved for use, and the CV benefit of that lowering has never been convincingly demonstrated, though niacin and PCSK9 antibodies have both been shown to lower Lp(a) by approximately 25%. With this new antisense technology, in early phase trials, reductions of 67% to 72% were achieved in trials of moderate doses, and at the highest dosing level, a 90% reduction was measured.[237] A more recent study reported dose-dependent Lp(a) reductions of up to 80%.[238] As the benefit of reducing Lp(a) by any means on CV risk is unknown, the drug will likely require a beneficial CV outcomes study to achieve regulatory approval. That study is currently being enrolled.

Acknowledgments

We express our gratitude to Caroline Diggins and Samuel Russo for their assistance in the revision of this chapter.

KEY POINTS

- The metabolic syndrome is a very common and often heritable disorder associated with obesity and insulin resistance.
- It predisposes to type 2 diabetes, atherosclerostic cardiovascular disease, certain cancers, and other diseases.
- It is treatable early with diet, exercise, and pharmacologic agents, all of which may function by activating AMP-activated protein kinase.

For the purposes of this review, we will define *metabolic syndrome* as a state of metabolic dysregulation characterized by insulin resistance, hyperinsulinemia, and a predisposition to type 2 diabetes, atherosclerotic cardiovascular disease (ASCVD), hypertension, Alzheimer disease, certain cancers, and many other disorders.[1-3] Affected individuals are typically (although not always) obese (body mass index [BMI] >29 kg/m^2) or overweight (BMI >25–29 kg/m^2), or they manifest more subtle manifestations of excess adiposity, such as increases in triglyceride deposition in intraabdominal fat,[4,5] liver, and skeletal muscle (ectopic liquid). In addition, they may present with low-grade inflammation, oxidative and endoplasmic reticulum (ER) stress, evidence of mitochondrial dysfunction, and an impaired ability to exercise (deceased VO_2 max).[3,6-24] From a clinical perspective, metabolic syndrome is important for several reasons. First, it can antedate ASCVD, type 2 diabetes, and other diseases to which it predisposes by many years.[1,2,10] Second, it may be both a casual factor for these diseases and a target for their prevention and therapy. Third, it is extremely common (see the following section). A pathophysiologic depiction of metabolic syndrome and its three hypothetical clinical phases, as perceived by the authors, is presented in Fig. 26.1. The potential importance of dysregulation of many of the factors listed in phase 2, including AMP-activated protein kinase (AMPK) and the sirtuins, will be discussed later.

DIAGNOSIS AND PREVALENCE

As evident from the preceding section and Fig. 26.1, a multitude of factors are associated with metabolic syndrome. Furthermore, clinically useful tests for some of these factors are sufficiently complex or vary too much among laboratories to prove clinically useful (e.g., plasma insulin levels). Likewise, others may vary between, and to some extent even within, racial or ethnic groups (e.g., waist circumference). Thus, the diagnostic criteria shown in Table 26.1 (Adult Treatment Panel III [ATP III] guidelines) apply to White individuals of European ancestry.

Metabolic syndrome (phases 2 and 3) in adults is currently diagnosed clinically by the presence of at least three of the following criteria: fasting plasma glucose greater than 100 mg/dL; blood pressure greater than 130/80 mm Hg; dyslipidemia; plasma triglyceride greater than 150 mg/dL; high-density lipoprotein (HDL) cholesterol less than 40 mg/dL (men) or less than 50 mg/dL (women); and increased waist circumference, with precise values dependent on sex and ethnic group (see Table 26.1).[1] Based on ATP III guidelines, in 2002 in excess of 50 million individuals older than 20 years of age in the United States had this diagnosis, and the number in 2014 was probably at least 50% higher (Fig. 26.2). In addition, the prevalence of metabolic syndrome is increasing rapidly in children and adolescents, in parallel with the pandemic of obesity in these age groups.[24] Based on both its natural history[21] and studies of the offspring of patients with associated disorders, metabolic syndrome is preceded by a preclinical state characterized by

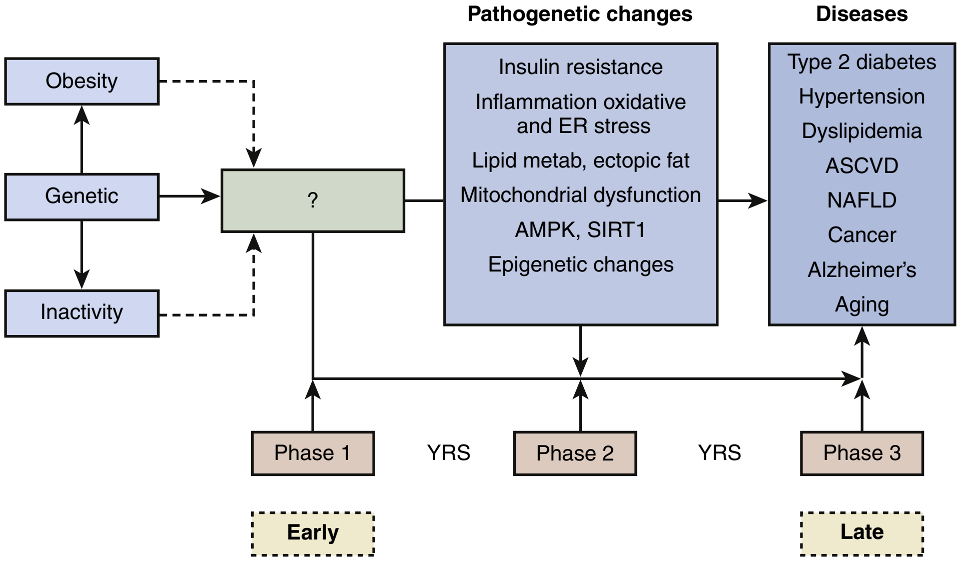

Figure 26.1 **Metabolic syndrome: a pathophysiologic overview and its three hypothetical clinical phases.** A combination of overnutrition, inactivity, and genetic and other factors interact to produce a state of metabolic dysregulation that leads to insulin resistance, ectopic lipid deposition with or without obesity, and, in many instances, inflammation, oxidative and endoplasmic reticulum (ER) stress, and other manifestations of cell dysfunction (phase 2). In individuals who are genetically predisposed, this in turn leads to one or more of the indicated disorders, many of which are associated with an increased risk for type 2 diabetes and atherosclerotic cardiovascular disease (ASCVD). Recent studies suggest that dysregulation of the AMP-activated protein kinase (AMPK) fuel-sensing and signaling network, and a closely related group of molecules, the sirtuins, may accompany these changes and could be both a causal factor and a target for their therapy. It is likely that one or more of the factors in phase 2 play a pathogenetic role in phase 1; however, this remains to be determined. Typically, systemic evidence of inflammation is not observed in phase 1, although abnormalities in mitochondrial gene expression, insulin resistance, and an altered capacity for exercise have been noted in young offspring of patients with type 2 diabetes. The transition from this preclinical phase to the clinically diagnosed metabolic syndrome (phase 2) to overt disease (phase 3) may take many years, with the rate of progression determined by environmental factors, such as diet and exercise, genetic predisposition, and pharmacotherapy for concurrent diseases.

TABLE 26.1 Adult Treatment Panel III Diagnostic Criteria for Metabolic Syndrome

Risk Factor	Defining Level
Abdominal Obesity (Waist Circumference)	
Men	>102 cm
Women	>88 cm
Triglycerides	>150 mg/dL
HDL Cholesterol	
Men	>40 mg/dL
Women	>50 mg/dL
Blood pressure	>130/80 mm Hg
Fasting glucose	>110 mg/dL*

*American Diabetes Association subsequently lowered fasting glucose level to 100 mg/dL.

HDL, High-density lipoprotein.

Data from Grundy SM, Brewer HB, Cleeman JI, et al. Definition of metabolic syndrome: report of the National Heart, Lung, and Blood Institute/American Heart Association Conference on scientific issues related to definition. *Circulation.* 2004;109:433–438.

insulin resistance, hyperinsulinemia, and modest increases in plasma triglycerides, blood pressure, and glucose that by themselves may not be considered significant even in young normal-weight individuals (phase 1).

HISTORY

Obesity, Type 2 Diabetes, Insulin Resistance, and Cardiovascular Disease

The clustering of the major components of metabolic syndrome, such as obesity, type 2 diabetes, hypertension, and dyslipidemia, has long been recognized[25]; however, its delineation as a distinct entity took place only after its linkage to insulin resistance, hyperinsulinemia, and cardiovascular disease (CVD) became more apparent.[21,26,27] *Insulin resistance* has been defined as a state (of a cell, tissue, system, or body) in which greater than normal amounts of insulin are required to elicit a normal biological response.[28] In humans, it is currently diagnosed on the basis of increased plasma insulin concentrations, either fasting or during a glucose tolerance test, or by a decreased rate of glucose infusion required to maintain euglycemia during a hyperinsulinemic-euglycemic clamp.[8] The much greater prevalence of insulin resistance in patients with type 2 than type 1 diabetes was appreciated 70 years ago by Himsworth and colleagues, based on their substantially higher insulin requirement[29,30] and diminished response to exogenous insulin.[31] Shortly after the development of the insulin immunoassay by Yalow and Berson in 1960,[32] this suspicion was confirmed,[33,34] and other disorders associated with insulin resistance and hyperinsulinemia were identified, including coronary heart disease and several of its risk factors,[21,35-40] as well as obesity itself (see Fig. 26.1). In general, most adults with insulin resistance and hyperinsulinemia are obese (BMI >29 kg/m^2) or overweight (BMI 25–29 kg/m^2). However, a significant

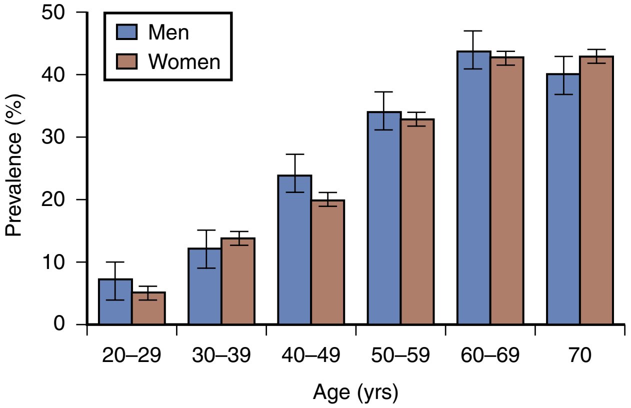

Figure 26.2 Prevalence of the metabolic syndrome in the United States according to age, based on National Health and Nutrition Examination Survey data and Adult Treatment Panel III criteria (see Table 26.1). Since these data were obtained, the criteria for abnormal glucose levels in patients with metabolic syndrome diminished from 110 mg to 100 mg. In addition, the prevalence of obesity and type 2 diabetes has increased in all of these age ranges and the general population (by as much as 50%). (Adapted from Ford ES, Giles WH, Dietz WH. Prevalence of the metabolic syndrome among US adults: findings from the third National Health and Nutrition Examination Survey. *JAMA.* 2002;287:356–359.)

percentage are normal-weight by BMI but show increases in visceral fat (central obesity),[4,8] increased ectopic lipid deposition in liver and skeletal muscle,[7,41] and/or enlarged fat cells.[5,42] The presence of central obesity has been shown to correlate strongly with an individual's predisposition to most of the diseases indicated in Fig. 26.1, including coronary heart disease,[43,44] and this is the reason waist circumference is one of the principal diagnostic criteria for metabolic syndrome, as discussed later.

Interestingly, hyperinsulinemia and insulin resistance are also present in normal-weight offspring of individuals with type 2 diabetes,[7,45-47] hypertension,[48] and hypertriglyceridemia[8,49,50] and in individuals at increased risk for coronary heart disease,[51-54] suggesting that they are early markers or pathogenetic factors for these disorders. Studies such as these, plus the presence of a high rate of ischemic heart disease in patients with type 2 diabetes at the time of diagnosis (20%–50%),[55-57] and to a somewhat lesser extent individuals with impaired glucose tolerance,[58] have led to the suggestion that treatment of metabolic syndrome at an early stage may be needed for preventing or at least delaying coronary heart disease.[8,22,39,59,60]

The presence of insulin resistance in otherwise normal offspring of patients with type 2 diabetes, hypertriglyceridemia, and hypertension has led to the notion that it is a causal factor for metabolic syndrome or an early pathogenetic event.[21] According to this widely held view, insulin resistance affects a number of organs (e.g., muscle, liver, adipose tissue, blood vessels), and hyperinsulinemia due to increased insulin secretion by the pancreatic β cell and decreased insulin degradation by the liver is a compensatory phenomenon.[14,21,35] The observation that therapies that increase insulin sensitivity and lower plasma insulin levels (e.g., lifestyle modification such as diet and exercise)[61-63] or treatment with metformin[61] and, to an even greater extent, the thiazolidinediones (TZDs)[64-65] prevent or delay the onset of diabetes in individuals with glucose intolerance is compatible with this notion, as is the efficacy of these therapies in some individuals with other disorders associated with metabolic syndrome, such as nonalcoholic fatty liver disease[66,67] and polycystic ovarian syndrome (PCOS).[68-70] Left unexplained by this hypothesis is the molecular mechanism by which insulin resistance develops initially and how it leads to hyperinsulinemia. Also, the possibility that hyperinsulinemia is the more primary of the two events or occurs simultaneously with the insulin resistance has not been ruled out.[70]

Hypothetically, metabolic syndrome could be related to genetic abnormalities in the insulin signaling cascade. In keeping with this possibility, mutations in *IRS1* and *IRS2,* which encode the initial targets of the insulin receptor tyrosine kinase, have been shown to lead to insulin resistance and diabetes in transgenic mice.[71,72] Evidence that these or other genetic defects in the insulin signaling cascade are common in humans with metabolic syndrome or type 2 diabetes and account for observed signaling defects[73] is still lacking, however.

KEY POINTS

- Metabolic syndrome is becoming increasingly common. As of 15 years ago, upward of 50 million individuals older than 20 years of age are affected in the United States, and the diagnosis is becoming increasingly common in children and adolescents.

The Lipid Theory

Insulin resistance and hyperinsulinemia in humans and experimental animals have been linked to obesity and dysregulation of cellular lipid metabolism in a wide variety of circumstances.[73-76] Early studies focused on fatty acid release from adipose tissue and assumed that insulin resistance occurs in skeletal muscle when plasma free fatty acid (FFA) levels are increased as a consequence of central obesity. More recently, it has become apparent that insulin resistance is associated with alterations in lipid metabolism in tissues other than skeletal muscle, and that a number of newly discovered hormones and intracellular regulatory mechanisms affect its appearance. In addition, it has been demonstrated that metabolic syndrome occurs in individuals who lack adipose tissue, as well as in those with excess adiposity, and that in both groups it is associated with triglyceride deposition in ectopic sites such as muscle, liver, and visceral fat. In this section, we will attempt to review the current status of this increasingly complex but intriguing area. We will discuss several distinct but often interrelated mechanisms that have been put forth to explain the link between altered lipid metabolism and components of metabolic syndrome.

Excess Free Fatty Acids. Over 50 years ago, Philip Randle and colleagues proposed the existence of a glucose–fatty acid cycle.[77] More specifically, they demonstrated that increased fatty acid levels diminish insulin-stimulated glucose utilization in a perfused rat heart preparation. They showed that this effect occurs within minutes, and that it is associated with enhanced mitochondrial fat oxidation that leads to both inhibition of glucose oxidation at the pyruvate dehydrogenase step and an increase in the cytosolic concentration of citrate. Randle and associates also demonstrated that the increase in citrate inhibited glycolysis at phosphofructokinase, and that the secondary increase in glucose 6-phosphate inhibited hexokinase and secondarily diminished insulin-stimulated glucose uptake[78] (Fig. 26.3). It was suggested that a similar mechanism in skeletal muscle may account for the insulin resistance observed in humans with obesity or type 2 diabetes, in both of whom plasma FFA levels were known to be elevated.[79] Over the next 25 years, most investigators were unable to reproduce these findings in skeletal muscle, however,[75,80-82] except in special circumstances.[83] For this reason, the acute contribution of elevated plasma FFA levels to the insulin resistance observed in most humans with obesity, type 2 diabetes, and other metabolic syndrome–associated disorders remained unclear.

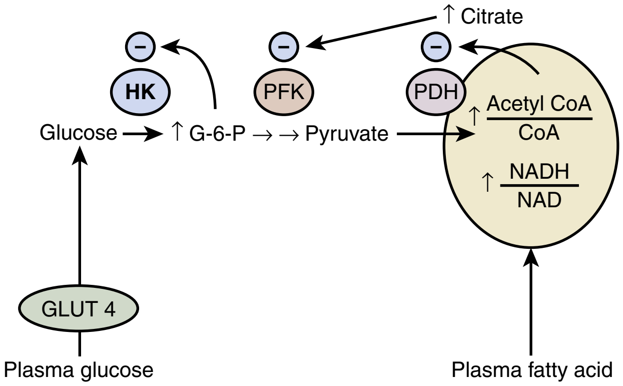

Figure 26.3 **Inhibition of glucose uptake and oxidation by fatty acids as described in heart muscle by Randle, Garland, Hales, and Newsholme (1964, 1965).** (See text for details.) (Adapted from Shulman GI: Cellular mechanisms of insulin resistance. *J Clin Invest.* 2000;106:171–176.)

This changed in 1991 when Boden and colleagues[84] definitively demonstrated that raising plasma FFAs (by infusing a lipid emulsion with heparin to activate lipoprotein lipase activity) in humans during a euglycemic-hyperinsulinemic clamp inhibits insulin-stimulated peripheral glucose uptake. Importantly, they found that this effect required 4 to 6 hours rather than a few minutes to become evident, and that it was not accompanied by an increase in citrate. Subsequent investigations by Shulman's laboratory in which ^{31}P magnetic resonance spectroscopy (MRS) was used to noninvasively measure intramyocellular glucose-6-phosphate found that its concentration was reduced under the same conditions, suggesting that fatty acids principally inhibit insulin-stimulated glucose transport or phosphorylation activity[85] and not the phosphofructokinase reaction, as suggested by Randle. Later, studies by the same group, in which ^{13}C MRS was used to assess intramyocellular glucose concentrations, revealed that insulin-stimulated glucose transport and not phosphorylation was the step inhibited by high plasma fatty acids, and that this defect was associated with lipid-induced defects in insulin-stimulated PI3 kinase activity.[86]

Other studies have demonstrated that insulin resistance in human muscle, caused by infusing lipids to increase plasma FFAs, is associated with impaired insulin signaling,[73] increases in the concentrations of muscle triglyceride, long-chain fatty acyl CoA[87] and diacylglycerol, and increases in protein kinase C (PKC) activity and the translocation of various PKCs from the cytosol to a membrane fraction.[76,88-90] Another key finding was a decrease in IKBα abundance, suggesting activation of NF-κB and proinflammatory events.[90] As discussed later, similar abnormalities have been found in rodent liver following a sustained exposure to fatty acids,[91-94] in rodent muscle in a wide variety of states associated with insulin resistance,[76,88,89] and in liver and muscle of massively obese insulin-resistant humans with type 2 diabetes.[95,96] Thus, the intracellular changes produced by an excess of fatty acids are associated with insulin resistance in many tissues.

A still unanswered question is whether an increase in plasma FFAs is an early pathogenetic event in metabolic syndrome. Elevated concentrations of plasma FFAs attributable to increased adipose tissue mass and the relative insensitivity of large fat cells and visceral fat to insulin[35,87] are present in individuals with obesity and type 2 diabetes, and they appear to contribute to insulin resistance when these disorders are established.[74,87,97,98] On the other hand, even some severely obese individuals remain insulin-sensitive (see later section entitled "Bariatric Surgery Patients: Insulin-Resistant and -Sensitive"), suggesting that other factors are involved.[99] It is also unclear whether plasma FFAs are elevated in individuals with metabolic syndrome in its very early stages. Only modest increases in plasma FFAs, if any, have been observed in normal-weight insulin-resistant individuals who are at risk for developing diabetes because of family history.[45,100]

Altered Fatty Acid Metabolism: Malonyl Coenzyme A, Mitochondrial Dysfunction, and Adenosine Monophosphate–Activated Protein Kinase. A second abnormality in lipid metabolism that could lead to insulin resistance is a disturbance in fatty acid metabolism in which the oxidation of cytosolic long-chain fatty acyl CoA (FACoA) by mitochondria is impaired, and its esterification and metabolism by other nonmitochondrial processes is enhanced.[76,101] This could occur if either the intrinsic ability of mitochondria to oxidize fatty acid is decreased or the activity of carnitine palmitoyltransferase 1, the enzyme that regulates the transfer of cytosolic long-chain fatty acyl CoA into mitochondria, is diminished.

Malonyl CoA. Altered fatty acid partitioning between the mitochondria and cytoplasm as a cause of insulin resistance was suggested by studies from the Ruderman laboratory in denervated rat muscle, in which enhanced diacylglycerol (DAG) synthesis and PKC activation were observed,[102] and later by similar findings in muscle of obese, insulin-resistant KKA^{y} mice.[103] In these and other instances, insulin resistance in rodent muscle correlated with an increase in the concentration of malonyl CoA,[76] an allosteric inhibitor of carnitine palmitoyltransferase. As shown in Fig. 26.4, an increase in malonyl CoA by decreasing the oxidation of cytosolic FACoA would increase its availability for the formation of DAG, triglycerides, ceramide, and possibly other factors linked to insulin resistance. In keeping with such a mechanism, McGarry concurrently demonstrated that treatment with etomoxir, a pharmacologic CPT1 inhibitor, both increases triglyceride accumulation and causes insulin resistance in rat skeletal muscle.[101,104] A number of other findings also support this notion: (1) mice lacking functional acetyl CoA carboxylase 2 (ACC$_2$, the principal isoform that generates the malonyl CoA that regulates CPT$_1$ in skeletal muscle) are more insulin-sensitive than control rats[105,106]; (2) the administration of an ACC inhibitor diminishes obesity and insulin resistance in fat-fed rats[107]; (3) antisense oligonucleotides directed at hepatic ACC1 and ACC2 diminish both hepatic steatosis and insulin resistance in mice fed a high-fat diet[108]; and (4) low rates of fatty acid oxidation have been reported in preobese humans,[109,110] Zucker diabetic rats,[111] and interleukin-6 (IL-6) knockout mice[112] prior to the onset of diabetes and obesity. Malonyl CoA was not assayed in muscle in any of these studies; however, in two of the rodent models[113,114] and in adipose tissue of obese insulin-resistant humans,[115,116] a decrease in the activity of AMPK was found, suggesting that its concentration was elevated (see later section entitled "AMP-Activated Protein Kinase").

Mitochondrial Dysfunction. Altered fatty acid partitioning in muscle and other tissues could also occur if fatty acid oxidation is depressed as a consequence of mitochondrial dysfunction. Decreases in mitochondrial function, and in some instances number and size, have been found in muscle of individuals with type 2 diabetes associated with obesity,[117] in lean insulin-resistant older adults,[118] and in lean insulin-resistant offspring of diabetic parents.[7] In the latter, the reduction in mitochondrial function was associated with a similar decrease in mitochondrial content.[119] Likewise, decreases in the mRNA for PGC1α, a transcriptional coactivator that enhances genes for mitochondrial biogenesis and function, have been observed in

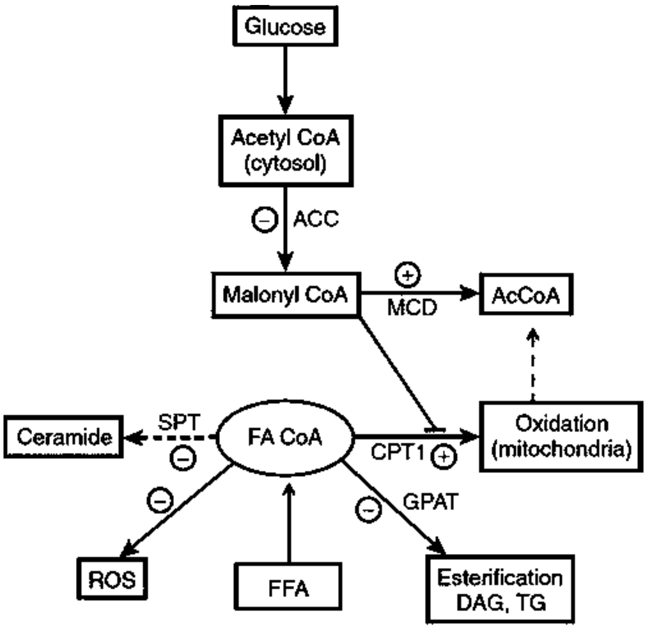

Figure 26.4 **AMP-activated protein kinase (AMPK) concurrently activates (+) or inhibits (–) multiple aspects of fatty acid and glucose metabolism.** By phosphorylating and inhibiting ACC and activating MCD, AMPK diminishes the concentration of malonyl CoA. This relieves the inhibition of CPT1 by malonyl CoA and results in both increased fatty acid oxidation and a decrease in the availability of cytosolic FACoA for TG, DAG, and ceramide synthesis, and possibly lipid peroxidation and protein acylation. Conversely, AMPK activation independently decreases the expression of glycerophosphate acyltransferase GPAT, fatty acid synthase *(not shown),* and SPT, decreasing the synthesis of glycerolipids, fatty acids (*de novo*), and ceramide (*de novo*), respectively. A decrease in AMPK produces the opposite effects. The basis for the ability of AMPK to inhibit oxidant stress (ROS generation) inflammation, and ER stress *(not shown)* in some settings is not completely understood. Whether AMPK activation enhances or inhibits a process or an enzyme in this scheme is denoted by *plus signs* and *minus signs,* respectively. Not shown in the diagram is that AMPK achieves these changes in some instances by phosphorylating the indicated enzyme and/or in other instances by regulating its expression at the level of the gene. For instance, AMPK can enhance mitochondrial biogenesis and function by enhancing the expression of the transcriptional coactivator PGC1α. *ACC,* Acetyl CoA carboxylase; *CPT1,* carnitine palmitoyltransferase 1; *DAG,* diacylglycerol; *FACoA,* cytosolic long-chain fatty acyl CoA; *GPAT,* glycerophosphate acyltransferase; *MCD,* malonyl CoA decarboxylase; *ROS,* reactive oxygen species; *SPT,* serine palmitoyl transferase. some[120] but not all[119] studies of nondiabetic first-degree relatives of patients with type 2 diabetes, as well as in individuals with type 2 diabetes and impaired glucose tolerance.[121] Whether these mitochondrial changes are hereditary or secondary to metabolic events (e.g., lipotoxic changes due to abnormalities in intracellular lipid metabolism) or abnormalities in AMPK regulation (see the following section) remains to be determined. However, given the likely role for increased intracellular fatty acid metabolites in mediating insulin resistance, impaired mitochondrial function leading to decreased fatty acid oxidation will almost certainly exacerbate the problem. Also to be determined is whether the changes observed in the offspring of diabetic parents reflect a difference in muscle fiber type, because the ratio of mitochondrial-rich type 1 fibers to glycolytic type 2 fibers may be decreased in these individuals.[7,122]

BOX 26.1 AMP-Activated Protein Kinase

AMP-activated protein kinase (AMPK) is a heterotrimer containing α, β, and γ subunits, each of which has at least two isoforms. The α subunit contains the catalytic site; the β subunit contains a glycogen-binding domain; and the γ subunit contains two AMP-binding sites. All three subunits are necessary for full activity.[298,299] In general, AMPK is found in the cytosol of a cell; however, the A2 isoform of the enzyme is also present in the nucleus.[299] Decreases in the energy state of a cell that lead to increased binding of AMP and ADP in place of ATP on the γ subunit activate AMPK by a number of mechanisms, including allosteric activation and especially covalent modification due to phosphorylation of its catalytic subunit on Thr-172 as a result of the actions of the AMPK kinase LKB1. In addition, factors that increase cellular Ca^{2+} and CaMKKb also activate AMPK.[300,301] When activated, AMPK enhances a number of processes that increase ATP generation, including fatty acid oxidation and glucose transport (in skeletal muscle), and it decreases others that consume ATP, but are not acutely necessary for survival, including to varying extents fatty acid triglyceride and protein synthesis. In addition, AMPK can alter the expression of a wide variety of genes, including several that alter mitochondrial function (e.g., *PGC1a, UCP3*) and lipid synthesis *(SREBPIC).*

AMP-Activated Protein Kinase. AMPK (Box 26.1) is a fuel-sensing enzyme that appears to play a key role in regulating both cellular metabolism and mitochondrial function. In addition, an increasing body of evidence has suggested that its dysregulation could be a cause of metabolic syndrome (animal studies) as well as a target for its prevention and therapy (human and animal studies).[3,75] Furthermore, it has been shown definitively in rodents that exercise *in vivo* (treadmill running) activates AMPK not only in muscle but also in liver, adipose tissue,[123] and aortic endothelium.[124]

As shown in Fig. 26.4, when AMPK is activated (e.g., during exercise or in some tissues by caloric deprivation), it phosphorylates and inhibits acetyl CoA carboxylase, the enzyme that catalyzes the synthesis of malonyl CoA and (by a still undetermined mechanism) activates malonyl CoA decarboxylase, the enzyme that catalyzes malonyl CoA degradation.[123] In addition, in many tissues and cells, activation of AMPK concurrently inhibits the use of cytosolic FACoA for the synthesis of various factors that could lead to insulin resistance, including DAG and ceramides, and it diminishes the generation of lipid peroxides, ER stress, and activation of NF-κB caused by elevated concentrations of specific fatty acids and other factors.[75,125,126,127] Furthermore, it can do so in multiple tissues and by cells such as macrophages, which could contribute to inflammation in various tissues.[128] Thus, AMPK could protect cells and tissues against lipotoxicity by multiple mechanisms. For instance, in addition to modulating the above events acutely by phosphorylating specific proteins, AMPK chronically regulates the effects of transcriptional regulators (e.g., SREBP1C) that govern the synthesis of acetyl CoA carboxylase and other key enzymes that regulate fatty acid oxidation (see Fig. 26.4). Of specific relevance to this chapter is that decreases in AMPK activity are associated with insulin resistance in muscle (Table 26.2) and liver in many situations, and failure to activate AMPK in the fat cell during lipolysis is associated with increases in oxidative stress and inflammation.[126] In addition, hormones and other factors that decrease AMPK in peripheral tissues, such as glucocorticoids[129] and resistin,[130] cause insulin resistance, whereas hormones (e.g., adiponectin and leptin) and pharmacologic agents (e.g., metformin, TZDs, α-lipoic acid, salsalate, AICAR) that activate AMPK diminish it in experimental animals, as does exercise[75] (Table 26.3). Finally, as already noted, closely linked to mitochondrial theories of insulin resistance is PGC1α (PPARγ-coactivator 1α), a transcriptional coactivator of mitochondrial biogenesis whose expression is increased when AMPK is activated (e.g., by exercise or AICAR).[131-134]

TABLE 26.2 Abnormalities Associated With Insulin Resistance in Tissues of Humans and Experimental Animals

Model	TG	DAG	Malonyl CoA	PKC Activity	Activated IKK-NF-kB	AMPK Activity
fa/fa rat	(+)	(+)	(+)	(+)	ND	(–)
Glucose-infused rat	(+)	(+)	(+)	(+)	ND	(–)
Fat-fed rat	(+)	(+)	(+/–)	(+)	(+)	ND
Fat-infused humans	(+)	(+)	ND	(+)	(+)	ND
Obese insulin-resistant humans	(+)	ND	(+/–)	(+)	ND	(+/–)

AMPK, AMP-activated protein kinase; *DAG,* diacylglycerol; IKK, inhibitor of NF-κB kinase; *NF-kB,* nuclear factor kappa B; *PKC,* protein kinase C; *TG,* triglyceride; (+), increased; (–), decreased; *ND,* not determined.

Data are for skeletal muscle. They are taken from Ruderman N, Prentki M. AMP kinase and malonyl-CoA: targets for therapy of the metabolic syndrome. *Nat Rev Drug Discov.* 2004;3:340–351 and are from the laboratories of the authors and those of Turinsky, Kraegen, Caro, Boden, and Shoelson. Many of these changes have also been demonstrated in liver in insulin-resistant obese humans, fat-fed and glucose-infused rats, and fa/fa rats. Whether AMPK activity is depressed and the concentration of malonyl CoA elevated in skeletal muscle of obese insulin-resistant humans is controversial; however, it has been clearly observed in adipose tissue (see the section entitled "AMPK and the Metabolic Syndrome in Humans"). Studies, primarily *in vitro*, suggest that similar events occur in the liver, pancreatic β cell, and cultured vascular endothelium.

TABLE 26.3 Effect of Therapies That Activate AMP-Activated Protein Kinase in Humans (H) and/or Rodents on Various Manifestations of the Metabolic Syndrome

Factor	Insulin Resistance	Pancreatic β Cell Dysfunction	Endothelial Cell Dysfunction	Coronary Heart Disease Risk	NAFLD/NASH
Exercise (H)	(–)	ND	(–)	(–)	(–)
Calorie/weight reduction (H)	(–)	(–)	(–)	(–)	(–)

Leptin	(–)	(–)	(–)	ND	(–)
Metformin (H)	(–)	(–)	(–)	(–)	(–)
TZDs	(–)	(–)	(–)	(–)	(–)
Polyphenols	(–)	ND	(–)	(–)	(–)

AICAR, 5-Aminoimidazole-4-carboxamide riboside; *AMPK,* AMP-activated protein kinase; *NAFLD/NASH,* nonalcoholic fatty liver disease/nonalcoholic steatotic hepatitis; *TZDs,* thiazolidinediones; *(–),* decreased; *ND,* not determined.

Where studied, these factors also alter ectopic lipid deposition in keeping with their effects on AMPK and malonyl CoA. Inactivity, caloric excess (glucose), and deficiencies of leptin or adiponectin, where studied, have been shown to have opposite effects. Studies with AICAR and experimental polyphenols (resveratrol, SI-17834) have only been carried out in rodents. Polyphenols stimulate AMP-activated protein kinase, lower lipids, and inhibit accelerated atherosclerosis in diabetic LDL receptor-deficient mice. Resveratrol improves health and survival of mice on a high-calorie diet.

Inflammation and Oxidative and Endoplasmic Reticulum Stress

In recent years, considerable attention has been given to the theories in which the combination of oxidative and ER stress and NF-κB activation play a central role in the pathogenesis of metabolic syndrome. As noted by numerous investigators, all of these factors have been linked to insulin resistance in humans and experimental animals with a wide variety of disorders.[9,10,135-140] Because of this, it has been suggested that an abnormality of the innate immune system could be a proximal event in the pathogenesis of metabolic syndrome.[10] Although this possibility cannot be disproven, and it is unquestioned that proinflammatory events and oxidative and ER stress are often an integral component of metabolic syndrome, a number of observations including the following suggest that dysregulation of lipid metabolism that can lead to oxidative and ER stress and inflammation is likely to be a more primary factor: (1) the close correlation of metabolic syndrome in its early stages with weight gain, central obesity, ectopic lipid deposition, and elevated plasma FFA levels; (2) the presence of metabolic syndrome and ectopic lipid deposition in humans and experimental animals deficient in peripheral adipose tissue (lipodystrophy) and the reversal of these abnormalities in rodents by the implantation of fat[141-143] and in humans and/or rodents by the administration of leptin,[144,145] adiponectin,[146] and in some instances TZDs, all of which activate AMPK[75]; (3) the observation that elevating plasma FFA levels in humans and rodents by itself acutely (hours) leads to insulin resistance and proinflammatory changes[87,90,147]; and (4) the very early occurrence of alterations in cellular lipid metabolism and mitochondrial function in normal-weight normoglycemic, young offspring of diabetic parents.[7] To our knowledge, evidence of a proinflammatory state has not been reported in the latter group. These considerations aside, the possibility that proinflammatory changes leading to alterations in lipid metabolism are the cause of metabolic syndrome has not been ruled out; indeed, studies in rodents suggest that TNFα-induced inflammation can lead to a decrease in AMPK activity in skeletal muscle.[148] In addition, it has recently been demonstrated that treatment with the antiinflammatory drug salsalate improves glycemic status modestly (less than 0.24% reduction in hemoglobin $A1_c$) and reduces systemic inflammation in obese adults at risk for developing type 2 diabetes.[149] This agent has also been shown to activate AMPK, however.[150] Because therapies that target lipid metabolism, oxidative stress, and in some instances inflammatory events have all been shown to diminish insulin resistance in specific situations,[94,136-138] what is clear is that these factors are almost certainly interrelated.

Figure 26.5 Hypothetical mechanisms for the activation of inflammasomes in adipose tissue of obese insulin-resistant subjects. A, It is proposed that increased free fatty acid release from lipid droplets in the adipocyte lead to changes in adjacent macrophages (ceramide, caspase 1 activation) that activate the inflammasome, which generates interleukin (IL)-1B and other inflammatory cytokines. **B,** Effects of AMP-activated protein kinase (AMPK) on events in the macrophage. The identity of the factor(s) that decrease AMPK activity in cells in which inflammasomes are found is uncertain, although oxidative stress and inflammatory cytokines such as IL-1B and TNFα could be factors. Not shown here is that activation of caspase 1 in the inflammasome complex cleaves and presumably inactivates SIRT1. ULK1, a regulator of the autophage lysosome is phosphorylated and activated by AMPK. (Adapted from Choi AM, Nakahira K. Figure 26.6 Hypothetical mechanism by which dysregulation of adipose tissue in an obese insulin-resistant individual leads to insulin resistance and dysfunction in liver, aorta, and possibly other tissues. Adipose tissue of such patients releases increased amounts of free fatty acids, reactive oxygen species, inflammatory cytokines, and decreased amounts of adiponectin, all of which could contribute to insulin resistance and dysfunction in other tissues. AMP-activated protein kinase activity is decreased in adipose tissue of such individuals and in liver, aorta, and in some studies, muscle; however, it is uncertain whether it causes or is a result of the above changes.

Specific Tissues

Adipose Tissue. A number of lines of investigation have linked abnormalities in adipose tissue to the pathogenesis of metabolic syndrome. They also indicate that this likely reflects abnormalities both in adipocytes and in macrophages and other inflammatory cells in the stroma.[128,151] Thus, as already noted, elevated plasma FFA levels, attributable to an increase in their release from adipocytes in grossly or centrally obese individuals, correlate with the presence of insulin resistance in most patients.[87,152] In addition, when the function of the adipocyte as a store for lipid is impaired,[141,142] as it is in many insulin-resistant obese individuals,[99] it has been proposed that the excess fatty acid release could be a key event leading to the generation of the inflammatory cytokines IL-1, IL-8, TNFα, and others by stromal macrophages (Fig. 26.5). As shown in Fig. 26.6, an increase in the release of these cytokines, as well as of reactive oxygen species and FFA (from the adipocyte), are thought to be largely responsible for the cellular dysfunction and decreased AMPK observed in liver and other tissues of obese individuals with metabolic syndrome. As reviewed recently by Steinberg and Schertzer,[128] an overwhelming body of evidence indicates that AMPK is at the crossroad of metabolically driven macrophage inflammation, presumably by controlling its mitochondrial metabolism. In keeping with this conclusion, they point to multiple studies showing that decreasing AMPK activity by various means increases inflammation in the macrophage, whereas AMPK activation decreases it.[128]

Adiponectin. A deficiency of the adipokine adiponectin, also referred to as ACRP30, has been most closely linked to insulin resistance in humans. It is produced exclusively or at least predominantly in adipose tissue and is present in the circulation in trimeric, hexameric, and high–molecular-weight (HMW) forms. The biological relevance of the three oligomers[153,154] and still other forms of adiponectin is not completely understood. These considerations aside, there is abundant evidence that low immunoassayable adiponectin levels in plasma (accounted for mainly by the HMW form) are present in obese insulin-resistant individuals and in individuals at risk for type 2 diabetes[146,155] and coronary heart disease,[156] even in the absence of overt obesity. In addition, polymorphisms of the adiponectin gene have been associated with metabolic syndrome in some populations and a predisposition to type 2 diabetes in others.[146]

Adiponectin, like exercise, activates AMPK and stimulates AMPK-mediated events such as glucose transport and fatty acid oxidation in muscle[157,158] and inhibition of glucose production in liver (in rodents).[159] In addition, adiponectin has antiinflammatory actions.[160] Whether the insulin-sensitizing effect of adiponectin is AMPK-mediated has not been proven definitively; however, treatment with TZDs increases plasma adiponectin, and the insulin-sensitizing effect of these agents and their ability to activate AMPK are both markedly attenuated in adiponectin knockout mice.[161,162] Furthermore, decreased levels of adiponectin are one of the hallmarks of bariatric surgery patients who are insulin-resistant,[163] as is decreased AMPK activity in their adipose tissue.[115,116]

Leptin. Since its discovery by Friedman and colleagues,[164] interest in leptin has for the most part focused on its role as an appetite suppressant. However, it has also been recognized for some time that leptin increases oxidative metabolism and fatty acid oxidation in peripheral tissues, owing both to a direct action[165] and to an effect on the hypothalamus that appears to be mediated by the sympathetic nervous system.[166] As first reported by Minokoshi and Kahn and their coworkers, both the direct and centrally-mediated effects of leptin on peripheral tissues are associated with AMPK activation,[167] whereas its action on hypothalamic nuclei is associated with a decrease in AMPK activity.[168]

When leptin is lacking or its receptor is not functioning in peripheral tissues, lipid accumulates and cellular damage may result. Unger and associates[169,170] have reported that, in the Zucker diabetic fatty (ZDF) rat, which lacks the leptin receptor, such ectopic lipid accumulation occurs in liver, muscle, and the pancreatic β cell, and that it antedates the presence of diabetes and pancreatic β cell apoptosis. Furthermore, it has been found that AMPK is deficient in tissues of these rats,[114] and that treatment with AICAR[114,171] and exercise, which also activates AMPK in these animals,[171] prevents ectopic lipid accumulation, pancreatic β cell damage, and the development of diabetes. More recent studies have found that the antidiabetic effects of leptin may be attributed to its inhibition of the hypothalamic-pituitary-adrenal axis, leading to reduction in lipolysis and hepatic gluconeogenesis.[172]

Vascular Endothelial Cells and Atherogenesis. An impressive case has been made that atherogenesis is essentially an inflammatory response to a variety of risk factors, and that the consequences of this response include acute coronary artery and cerebrovascular syndromes.[173] An early site at which this inflammatory response appears to occur is the endothelial cell[173]; indeed, increases in NF-κB expression have been observed in endothelium at sites predisposed to atherosclerotic plaque formation[175] and *in vitro* in endothelial cells exposed to elevated concentrations of glucose[176] and fatty acids.[177] Likewise, impaired endothelium-dependent relaxation and increases in circulating adhesion molecules (VCAM1, ICAM, selectins), markers of cellular dysfunction and incipient ASCVD, have been observed in humans with type 2 diabetes and metabolic syndrome[135,178] and in normal individuals in whom plasma FFA levels are increased by a lipid infusion.[179] Conversely, endothelial cell dysfunction is diminished in humans by factors that diminish the proinflammatory state, including exercise and caloric restriction[180,181] and by treatment with TZDs.[178,182] As already noted, all of these interventions have been reported to activate AMPK in rodents. Studies with endothelial cells in culture also support such a protective role for AMPK. Thus, increases in oxidative stress and NF-κB–mediated gene expression observed in cultured human umbilical vein endothelial cells (HUVECs) incubated with palmitate are inhibited by AICAR and other AMPK activators.[125,183,184] Also, AICAR and (where studied) expression of a constitutively active AMPK have been shown to inhibit apoptosis, mitochondrial dysfunction, DAG synthesis, and the development of insulin resistance (diminished Akt activation) in HUVECs incubated in a high-glucose medium.[185] Finally, it has been demonstrated that the administration of atorvastatin, a cholesterol-lowering agent, by gavage activates AMPK and eNOS in the rat aorta,[186] and it has a similar effect when incubated with HUVECs. Whether this accounts for the antiatherogenic effect of statins attributed to its antiinflammatory action is an intriguing possibility.[187] Finally, it has long been appreciated that increases in macrophages are a hallmark of arteries undergoing atherosclerotic changes. As recently reviewed, an increasing body of evidence strongly suggests that treatments that activate AMPK combat atherosclerosis by diminishing proinflammatory events in macrophages, as they do in adipose tissue and presumably other sites.[128]

Liver. Changes similar to those in muscle and the endothelial cell occur in the liver in insulin-resistant states. Thus, as in muscle, an association between hepatic lipid deposition and insulin resistance has been clearly demonstrated in humans.[188,189] Also, in rats infused with a lipid emulsion to increase plasma FFA levels during a euglycemic-hyperinsulinemic clamp[91,147] or with short-term fat feeding,[93] the development of hepatic insulin resistance is associated with increases in DAG content, PKC activation, and a decrease in IKBα abundance—changes almost identical to those observed in human muscle.[90] Similar alterations in PKC have been noted in the livers of massively obese, insulin-resistant humans[95,190] and of fat-fed rats with hepatic steatosis.[93] Also, knockdown of PKC epsilon expression by antisense oligonucleotides protects rats from fat-induced hepatic insulin resistance.[191] As discussed later, bariatric surgery in such rodents is followed by increases in the activity of AMPK, SIRT1, and LKB1 in liver, as well as an increase in insulin sensitivity.[192]

Pancreatic β Cell. Insulin resistance in muscle and liver does not initially result in hyperglycemia, because it is accompanied by hyperinsulinemia. As noted previously, it is unclear whether the hyperinsulinemia is compensatory or results from the same factors that cause insulin resistance, in which event it may occur at the same time or even precede it.[70,193] In this context, it is noteworthy that increases in plasma FFA have been shown acutely to increase insulin secretion in certain settings, whereas chronic increases in the concentration of saturated fatty acids and glucose cause dysfunction and damage to the β cell and ultimately result in apoptosis.[75,101,194] Work from a number of laboratories[169,170,195,196] has both delineated the events that lead to these phenomena in the β cell and revealed their similarity to the changes observed in endothelium and other cells when exposed to high concentrations of FFAs or glucose. As already noted, in the ZDF rat, the leptin-receptor–deficient rodent characterized by Unger,[169] the activity of AMPK in multiple tissues is depressed, and treatment with troglitazone or AICAR or caloric deprivation prevents or at least markedly attenuates the development of β cell damage and dysfunction and hyperglycemia.[114,197] Likewise, it has been demonstrated that AMPK activation prevents the apoptosis and mitochondrial dysfunction observed in pancreatic β cells when incubated with saturated fatty acids at a high glucose concentration.[195] Finally, although theories linking triglyceride accumulation to β cell dysfunction are attractive and have led to interesting hypotheses,[22,182,198,199] to our knowledge there have been no definitive studies showing that triglyceride accumulates in human islets in patients with type 2 diabetes.

Molecular Mechanisms of Insulin Resistance and Cellular Dysfunction According to the Lipid Theory (Muscle and Liver). Based on studies reviewed in the preceding sections, a model can be proposed in which insulin resistance and cellular dysfunction in liver and muscle are due to an increase in intracellular fatty acid–derived molecules and metabolites such as fatty acyl CoA DAG[89,91,200] and ceramides, possibly secondary to dysregulation of AMPK (Fig. 26.7; see Table 26.2). According to this scheme, such changes activate a serine-threonine kinase cascade that includes conventional and/or novel protein kinase C isoforms,[89,91,201,202] IKKB,[203,204] and Jun-activated kinase, one or more of which phosphorylate serine residues on IRS-1 in muscle, and likely other tissues.[87] Similar changes in IRS1 in response to hyperglycemia may also result from activation of the mTOR/p70s6k signaling mechanism.[205] Serine phosphorylation of IRS-1 in turn impairs its ability to associate with P13-kinase, leading to diminished activation by insulin of Akt and PKC zeta, glucose transport, glycogen synthesis, and other downstream events. Studies demonstrating that transgenic mice with a muscle-specific alteration in IRS-1 Ser→Ala are protected from fat-induced insulin resistance in skeletal muscle strongly support this hypothesis.[206] Similar changes appear to occur in liver, except that the inhibitory actions of insulin on gluconeogenesis and glycogenolysis are impaired,[87,93,191] and IRS1 and IRS2 may be differentially affected.[207] Also possibly involved in this chain of events are increases in oxidative and ER stress, ceramide synthesis, NF-κB activation, and NF-κB–mediated gene expression that could explain, at least in part, the proinflammatory state associated with metabolic syndrome.[73,75,136] Interestingly, the hallmark of this insulin-resistant state is an increase in intracellular triglyceride in liver and muscle that can be quantified noninvasively with magnetic resonance imaging.[208,209] Triglyceride accumulation in muscle and liver is generally regarded as a marker of lipid-induced insulin resistance and cellular dysfunction, rather than a cause.[210] On the other hand, by providing an additional source of intracellular FFAs, it could play a more pathogenetic role.

The Hypothalamus, Food Intake, and Insulin Resistance. Leptin, which activates AMPK in peripheral tissues by a direct action, diminishes AMPK activity in the hypothalamus. This in turn leads to decreased food intake and activation of the sympathetic nervous system and, secondary to this, further activation of AMPK in peripheral tissues.[205] Conversely, glucocorticoids increase AMPK in the hypothalamus, leading to an increase in food intake, and they decrease AMPK and cause insulin resistance in peripheral tissues (see discussion of Cushing syndrome in the section entitled “AMPK and Metabolic Syndrome in Humans” later in the chapter and in Christ-Crain and associates[129]). Various antipsychotic drugs have also been found to activate AMPK in the hypothalamus, and, like glucocorticoids, they increase food intake and cause insulin resistance.[211] Why some agents that decrease or increase AMPK activity in the hypothalamus have opposite effects on peripheral tissues is not known. On the other hand, the possibility that a drug that activates or inhibits AMPK activity in peripheral tissues has the opposite effect in the hypothalamus or elsewhere in the central nervous system needs to be considered in evaluating its clinical efficacy and side effects.

KEY POINTS

- An increasing body of evidence suggests that a likely pathogenetic mechanism in most patients is an abnormality of cellular lipid metabolism that causes lipotoxic changes, including: insulin resistance, oxidant and ER stress, inflammation, and mitochondrial dysfunction in one or more tissues. Proposed causes of these abnormalities in cell lipid metabolism are elevated plasma FFA levels, dysregulation of AMPK, SIRT1, or malonyl CoA, and primary mitochondrial defects.

AMPK and SIRT1

Sirtuins are a group of histone 1 protein deacetylases that are regulated by changes in the cellular redox state ($NAD^+/NADH^+$ ratio) and increases in nicotinamide phosphoribosyltransferase (NAMPT), the rate-limiting enzyme for NAD synthesis. The seven sirtuins, and in particular SIRT1, the most studied member of the family, were evaluated initially because of their role in combatting aging.[212] As reviewed elsewhere,[213] SIRT1 responds to overfeeding, starvation, changes in energy expenditure, and exercise, as well as to adiponectin, much as does AMPK, although with somewhat different timing.[13,54,213] Interestingly, it has been shown that SIRT1 can activate AMPK by deacetylating its activator LKB1, which promotes its translocation from the nucleus to the cytosol, where LKB1 is activated, and it in turn phosphorylates and activates AMPK (which is already substantially located in the cytosol).[127,214,215] Conversely, AMPK can activate SIRT1 by increasing the $NAD^+/NADH$ ratio or the expression/activity of NAMPT.[216] These findings suggest the existence of an AMPK/SIRT1 cycle that links the cell’s energy and redox states.[217] In keeping with this notion, AMPK and SIRT1 (and probably other sirtuins) act on common transcriptional activators and coactivators, including members of the FOXO family and PGC1. In addition, both AMPK and SIRT1 activators have been shown to decrease atherosclerosis and prevent diabetes in experimental animals.[75,217,218] The latter could be related, at least in part, to the fact that changes in both AMPK and SIRT1 appear to exert effects on inflammation and fuel metabolism in M1 macrophages and T helper cells, both of which are more numerous in inflamed adipose tissue.[148] How AMPK and SIRT1 may interact with each other and with NF-κB and oxidative and ER stress in these cells to combat metabolic syndrome is illustrated in Fig. 26.8.

AMPK and Metabolic Syndrome in Humans

Although existing data in rodents with decreased AMPK activity and the beneficial effects of exercise and various pharmacologic agents that activate AMPK have linked it to metabolic syndrome in humans,[219] until recently, direct AMPK measurements in muscle of insulin-resistant humans were not strongly supportive, or yielded mixed results.[212] Since then, decreased AMPK activity has been clearly demonstrated in adipose tissue of two distinct groups of insulin-resistant individuals.

Cushing Syndrome. Korbonits and coworkers[220] observed decreased AMPK activity in the visceral fat of patients with Cushing syndrome, most of whom had elevated plasma cortisol levels due to a functioning adrenal adenoma. Such individuals are classically characterized by insulin resistance, visceral adiposity, hypertension, type 2 diabetes, and a predisposition to ASCVD and other diseases. Similar abnormalities also have been observed in patients treated with high doses of glucocorticoids for extended periods, although whether the incidence of ASCVD is increased is somewhat controversial.[221] Also of note, in contrast to most individuals with metabolic syndrome, patients with Cushing syndrome show little, if any, evidence of inflammation, and

Figure 26.7 **Proposed mechanisms for fatty acid induced insulin resistance in skeletal muscle (A) and liver (B).** **A,** Muscle. Increases is intramyocellular LCCoA and DAG, due to increased fatty acid delivery and/or decreased mitochondrial fatty acid oxidation, trigger a serine/threonine kinase (Ser/Thr) cascade initiated by nPKCs and possibly involving IKKB and/or JNK-1. This ultimately induces serine/threonine phosphorylation of critical IRS-1 sites in muscle, which inhibit IRS-1 tyrosine phosphorylation and activation of PI 3-kinase. This in turn results in reduced insulin-stimulated glucose transport and glycogen synthesis. **B,** Liver. Increases in intracellular DAG, due to enhanced lipogenesis and/or decreased mitochondrial fatty acid oxidation, activate PKCs (ε and/or possibly δ), which bind to and inactivate the insulin receptor kinase. This results in reduced insulin-stimulated IRS-1 and IRS-2 tyrosine phosphorylation, and decreased insulin activation of PI3-kinase and AKT2. This in turn leads to diminished GSK3 and FOXO phosphorylation, which decrease insulin-stimulated liver glycogen synthesis and hepatic gluconeogenesis, respectively. *DAG,* Diacylglycerol; *FOXO,* forkhead box protein O; *GLUT,* glucose transporter; *G6P,* glucose-6-phosphate; *GSK3,* glycogen synthase kinase 3; *IRS,* insulin receptor substrate; *IKKB,* IκB kinase β; *JNK-1,* Jun-activated kinase 1; *LCCoA,* long-chain acylcoenzyme A; *PEPCK,* phosphoenolpyruvate carboxykinase; *PI3-kinase,* phosphatidylinositol-3-kinase; *PTB,* phosphotyrosine-binding domain; *PH,* pleckstrin homology domain; *SH2,* src homology domain. Figure 26.8 Proposed interrelations of AMP-activated protein kinase (AMPK) and sirtuins 1 and 3 (SIRTs) with oxidative and ER stress and inflammation. AMPK and SIRT1 both activate each other and diminish oxidative and endoplasmic reticulum (ER) stress and low-grade inflammation in various settings. Conversely, oxidative and ER stress and inflammation, which activate each other, appear to diminish AMPK and SIRT1. In principle, any of these factors could be targeted to combat insulin resistance and the development of metabolic syndrome–associated disorders; however, to date, the most success has been observed with therapies that target AMPK. (Adapted from Ruderman NB, Carling D, Prentki M, et al. AMPK, insulin resistance and the metabolic syndrome. *J Clin Invest.* 2013;123:2764–2772,)

to our knowledge ER stress in adipose tissue has not been studied. In what respects the lack of these abnormalities in patients with Cushing syndrome distinguishes them from most other individuals with metabolic syndrome in whom they are present has yet to be determined.

Bariatric Surgery Patients: Insulin-Resistant and -Sensitive.

Perhaps even more compelling evidence of a link between decreased AMPK in adipose tissue and metabolic syndrome–associated disorders has been provided by studies in severely obese patients undergoing bariatric surgery. Gauthier and colleagues[116] and Xu and associates[115] observed that AMPK activity is significantly diminished (30%–50%), and that chronic oxidative stress (protein carbonylation) increased in adipose tissue of the 75% of such individuals who were insulin-resistant compared with equally obese subjects who were insulin-sensitive (homeostasis model assessment insulin resistance 6.7 vs. 2.3). They also observed that AMPK activity and mitochondrial gene expression were lower in visceral fat than in subcutaneous fat in both groups, and that the expression of inflammatory genes was lower in both fat depots in the patients with insulin resistance.[115] In another study of bariatric surgery patients in which AMPK was not measured, infiltration of adipose tissue with macrophages and decreases in plasma adiponectin (an AMPK activator) were the strongest correlates of insulin resistance.[163] These studies in adipose tissue have interesting implications, because bariatric surgery reverses type 2 diabetes and other disorders associated with metabolic syndrome, including dyslipidemia, hypertension, and PCOS.[24,151] It also diminishes long-term mortality from coronary heart disease (30%–50% at 20 years),[222] and the prevalence of solid tumors (by 70% 5 years postsurgery).[151] Interestingly, the beneficial effect of the surgery on coronary heart disease was most prominent in patients in the two highest quintiles of plasma insulin concentration preoperatively.[222] As noted earlier, such individuals have been found to be insulin-resistant, with decreased AMPK activity and increased oxidative stress, inflammation, and presumably ER stress and decreased mitochondrial function in their adipose tissue.[213] Whether the decreases in AMPK and, when it occurs, SIRT1 in adipose tissue of these patients increases rapidly post–bariatric surgery is not known. Interestingly, in rats made obese by fat-feeding, substantial increases in AMPK and SIRT1 and LKB1 activity were observed in liver 9 weeks after bariatric surgery.[192] Possibly other factors contribute to differences between severely obese individuals who are insulin-sensitive and insulin-resistant, including differences in their microbiome, collagen VI deposition, and lipid droplet proteins,[213] all of which have yet to be intensively examined. With respect to the microbiome, it has been shown that germ-free mice are characterized by a substantial increase in AMPK activity,[223] suggesting that bacteria and possibly the inflammation they cause diminish AMPK activity in mammalian organisms.

DIAGNOSIS

No single definitive diagnostic test for metabolic syndrome is yet available. As discussed earlier, historically it has been diagnosed based on the presence of general or abdominal obesity, dyslipidemia, hypertension, and impaired fasting glucose or glucose intolerance in various combinations. In addition, the presence of premature coronary heart disease, type 2 diabetes in its early stages, and other disorders associated with insulin resistance have sometimes been considered diagnostic criteria. Several organizations have published standards for diagnosis, including the National Cholesterol Education Program, ATP III, and the World Health Organization (WHO).[224] They differ principally in that the WHO criteria place more emphasis on measures of insulin resistance, the presence of microalbuminuria, and the use of the glucose tolerance test, whereas the ATP III emphasizes abdominal obesity and risk factors for CVD such as dyslipidemia and hypertension. A more recent set of criteria proposed by the International Diabetes Federation is similar to that of the ATP III but with somewhat lower cutoff points for blood pressure and fasting glucose.[17] In part because of its relative simplicity, for clinical purposes the ATP guidelines (see Table 26.1) appear to be in widest use. On the other hand, they probably underestimate the prevalence of insulin resistance in the general population.[225] Also of note is that modified criteria have been developed for different ethnic groups, because metabolic syndrome is not as closely associated with obesity (based on BMI) in some groups (e.g., South Asians) as it is in Caucasians.[17,226]

CORONARY HEART DISEASE AND TYPE 2 DIABETES

The notion that metabolic syndrome, or its surrogate markers hyperinsulinemia and insulin resistance, antedate and contribute to the pathogenesis of coronary heart disease, diabetes, and at least some cases of hypertension was proposed many years ago.[21,35] Coronary heart disease in the setting of metabolic syndrome can to a great extent be attributed to dyslipidemia (increased dense low-density lipoprotein [LDL] cholesterol, diminished HDL cholesterol, and hypertriglyceridemia),[227] as well as to elevations in blood pressure and blood glucose and the presence of a procoagulant, proinflammatory state.[22,224] In addition, some studies suggest that hyperinsulinemia and insulin resistance, as well as hyperglycemia, may be independent risk factors.[51] Whether elevated FFA levels or a dysregulation of intracellular fatty acid metabolism contribute to atherosclerosis by directly altering the function of endothelium (see the section entitled "Vascular Endothelial Cells and Atherogenesis") or other cells in the vascular wall remains to be determined. Relevant to this discussion, low levels of adiponectin are associated with an increased risk for coronary heart disease in humans,[156] whereas, as noted earlier, overexpression of adiponectin or its globular subunit diminishes the severity of atherosclerosis in ApoE–/– mice.[228,229]

More definitive evidence that metabolic syndrome *per se* predisposes to coronary heart disease and cerebrovascular disease has been

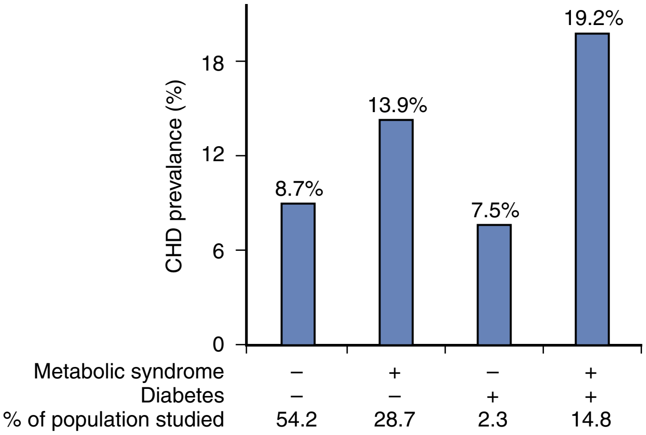

Figure 26.9 **Age-adjusted prevalence of CHD in the US population over 50 years of age, categorized by the presence of metabolic syndrome (Adult Treatment Panel III criteria) and diabetes.** Data are from the National Health and Nutrition Examination Survey study. The complete absence of an increase in CHD incidence in the diabetic patients without metabolic syndrome should be viewed with caution because of the small size of this group. *CHD,* Coronary heart disease. The role of skeletal muscle insulin resistance in the pathogenesis of the metabolic syndrome. *Proc Natl Acad Sci USA.* 2007;104:12587–12594.)

reported. Thus, a 2-fold to 4-fold increase in subsequent cardiovascular events has been described in men and women with metabolic syndrome (modified WHO criteria) even in the absence of type 2 diabetes or impaired glucose tolerance.[230-232] Qualitatively, similar results have been obtained when metabolic syndrome is defined by ATP III criteria[23,73,234] (Fig. 26.9). In a compilation of multiple studies, the presence of metabolic syndrome had a greater impact on the risk for developing diabetes (5-fold) than ASCVD (2-fold).[22,182,199] In addition, where studied, the rate of cardiovascular events was higher in patients who had diabetes and metabolic syndrome than in individuals with only metabolic syndrome.[22,235]

KEY POINTS

- In both adolescents and adults, metabolic syndrome substantially increases the risk for type 2 diabetes, coronary heart disease, and other associated disorders.

LINKAGE OF METABOLIC SYNDROME TO OTHER DISORDERS

From a practical point of view, the ATP III and WHO guidelines focus on the relationship of metabolic syndrome to obesity and the risk for developing type 2 diabetes and ASCVD. However, insulin resistance and hyperinsulinemia are also associated with other disorders in individuals who, for genetic or other reasons (e.g., drug therapy), are more susceptible to them. A few of these disorders will be briefly discussed.

Nonalcoholic Fatty Liver Disease and Nonalcoholic Steatohepatitis

It was estimated over 10 years ago that nearly 20 million individuals in the United States have the diagnosis of nonalcoholic fatty liver disease (NAFLD), and approximately 10% of these individuals develop nonalcoholic steatohepatitis (NASH), a disorder characterized by mitochondrial dysfunction, increases in oxidative stress and cell cytokines, and a predisposition to cirrhosis (approximately 20% of patients with NASH), and less commonly hepatocellular carcinoma.[67,236-239] NAFLD is also seen with increasing frequency in children and adolescents in parallel with the increasing prevalence of obesity in these populations.[240] Presumably, mildly abnormal liver function tests in the presence of obesity or type 2 diabetes or other manifestations of insulin resistance would help to identify individuals with NAFLD at an early point in time. Recent studies in young, lean, insulin-resistant individuals have demonstrated that insulin resistance in skeletal muscle, as reflected by decreased glycogen synthesis, can promote atherogenic dyslipidemia by changing the fate of ingested carbohydrate away from skeletal muscle glycogen synthesis into hepatic *de novo* lipogenesis, resulting in an increase in plasma triglyceride concentrations and a reduction in plasma HDL concentrations (Fig. 26.10). Furthermore, insulin resistance in these subjects was independent of changes in the plasma concentrations of TNFα, IL-6, HMW adiponectin, resistin, retinol-binding protein 4, or intraabdominal obesity, suggesting that these factors do not play a primary role in causing insulin resistance in the early stages of metabolic syndrome.[241] Further evidence in support of this hypothesis comes from a recent study that found that a single bout of exercise was sufficient to promote increased muscle glycogen synthesis and decreased *de novo* lipogenesis and hepatic triglyceride synthesis following carbohydrate ingestion in young, lean individuals with muscle insulin resistance.[242]

Polycystic Ovarian Syndrome

Another common disorder that becomes more prevalent in the presence of metabolic syndrome is PCOS.[68,69] PCOS is characterized by genetically determined increases in ovarian androgen production and disordered gonadotropin secretion that may be exaggerated by hyperinsulinemia or insulin resistance. Perhaps because of its association with metabolic syndrome and often, although not always, with obesity, PCOS is a leading risk factor for glucose intolerance and type 2 diabetes in adolescent and premenopausal women.[243] It may also increase their risk for premature CVD.[244] PCOS is associated with increases in such inflammatory factors as plasminogen activator inhibitor, C-reactive protein, and TNFα.[68] Like NAFLD/NASH, type 2 diabetes, and other disorders associated with metabolic syndrome, PCOS often responds to treatments that activate AMPK and/

For diabetic children and adolescents, diet and exercise are the recommended therapy. Where possible, however, metformin and insulin are often used. Data from Alberti G, Zimmet P, Shaw J, et al. Type 2 diabetes in the young: the evolving epidemic: the International Diabetes Federation Consensus Workshop. *Diabetes Care*. 2004;27:1798–1811.

or lower the concentration of malonyl CoA, such as diet and exercise, metformin, and TZDs[68] (see later section entitled “Treatment of Metabolic Syndrome”).

Certain Cancers

The reason for the link between metabolic syndrome, obesity, type 2 diabetes, and cancers of the colon, breast, liver, and other sites is less clear. It has generally been held that insulin-like growth factor 1 (IGF-1) could be one factor, because insulin both stimulates the synthesis of IGF-1 by liver and inhibits the synthesis of its binding protein IGFBP-1.[245] Another possibility relates to the fact that an upstream kinase that activates AMPK is LKB1,[246,247] a tumor suppressor that is deficient in individuals with Peutz–Jeghers syndrome and places them at increased risk for developing carcinomas of the colon, stomach, and pancreas and adenocarcinomas of the lung. The possibility that LKB1 and AMPK link metabolic syndrome to these cancers and are targets for their prevention or therapy warrants consideration.[248-250] Of note, agents that activate AMPK, such as metformin, have been shown to diminish the growth of cancer cells.[251]

Alzheimer Disease

Alzheimer disease and other disorders associated with dementia are more common in individuals with metabolic syndrome and type 2 diabetes. As reviewed elsewhere,[252] Alzheimer disease appears to be associated with insulin resistance as well as inflammation and mitochondrial dysfunction in the brain. Also of note, physical activity, which has been shown to activate AMPK in many tissues in rodents,[123] has demonstrated efficacy for preventing and treating Alzheimer disease in both humans and experimental animals.[3,252] Likewise, benefits from treatment with TZDs and metformin have been reported in some studies.[253]

Cushing Syndrome and Related Disorders

As already noted, patients with primary Cushing syndrome or Cushing syndrome due to therapy with glucocorticoids typically demonstrate central obesity, insulin resistance, hyperinsulinemia, and a predisposition to diabetes and hypertension.[254] In addition, like other patients with this clustering of events, they may be at increased risk for ASCVD.[255,256] The value of treatments aimed at AMPK and malonyl CoA in individuals with Cushing syndrome, when its primary cause cannot be corrected, has to our knowledge not been evaluated. It is noteworthy, however, that glucocorticoids diminish AMPK in peripheral tissues in rodents and, as discussed earlier, AMPK activity is decreased in visceral fat of patients with Cushing syndrome.[129] The possibility that an increase in cellular 11-β-dehydrogenase activity resulting in local increases in cortisol could be a cause of metabolic syndrome has been discussed elsewhere.[257]

Lipodystrophy

Patients with primary lipodystrophy and lipodystrophy secondary to drug therapy (e.g., protease inhibitors in HIV patients) appear to be subject to the same lipotoxicity observed in individuals with metabolic syndrome for other reasons. Two factors appear to contribute to an insulin-resistant state in these patients: (1) decreased peripheral fat cells cause more plasma FFA and lipoprotein triglyceride to be shunted to ectopic sites, and (2) plasma leptin and adiponectin levels are very low. The importance of the latter is suggested by successes in treating some patients with leptin[144,145] or with TZDs.[258] Interestingly, in the latter study, the beneficial effect of rosiglitazone was accompanied by an increase in adiponectin but not in subcutaneous fat mass.

Hyperalimentation

As suggested by Unger,[259] hyperalimentation can cause lipotoxic damage and, by inference, metabolic syndrome in some individuals. He hypothesized that at one extreme are normal individuals who eat an excess number of calories for an extended period and become hyperinsulinemic and insulin-resistant when the ability of their adipose tissue to deposit the excess lipid in their diet is exceeded.[260] At the other extreme are hyperalimented patients with an extensive loss of subcutaneous adipose tissue due to third-degree burns. Such burn patients are historically very insulin-resistant, which can be attributed at least in part to increased plasma concentrations of inflammatory cytokines, such as TNFα and IL-6. It remains to be determined if the burns contribute to their insulin resistance and whether the latter responds to pharmacologic agents that enhance insulin sensitivity.

Additional Disorders. Metabolic syndrome has also been associated with an increased prevalence of such disorders as gout, sleep apnea, gallstones, and chronic kidney disease.[199] Like other metabolic syndrome–related disorders, they are associated with obesity, type 2 diabetes, and a predisposition to ASCVD.

KEY POINTS

- The prevalence of metabolic syndrome is markedly increased in individuals who lack adipose tissue, as well as in individuals who are obese. In both populations, a common occurrence is ectopic lipid deposition in muscle, liver, and often visceral fat.

TREATMENT OF METABOLIC SYNDROME

The demonstration that metabolic syndrome increases the risk for developing other disorders in both otherwise normal individuals with type 2 diabetes strongly suggests that it warrants treatment (Table

26.4). Less clear are which therapies should be used in a given circumstance and when they should be started.

Lifestyle Modification (Weight Loss and Physical Activity)

The treatment of metabolic syndrome with the aim of preventing CVD has been reviewed by a clinical conference jointly sponsored by the American Heart Association, the National Heart, Lung and Blood Institute, and the American Diabetes Association (AHA/NHLBI/ADA). The consensus was that lifestyle modifications consisting of diet for the treatment of obesity and overweight and physical activity were the first line of therapy.[224,261,262] The efficacy of this approach for preventing disease has not been assessed specifically in patients with metabolic syndrome diagnosed by ATP III or WHO criteria; however, exercise has been shown to reverse the defects in insulin-stimulated glucose transport and muscle glycogen synthesis in young, lean, insulin-resistant offspring of parents with type 2 diabetes,[46] and in several prospective studies[61-63] the combination of diet and exercise has proven quite effective in delaying or preventing the onset of diabetes in patients with impaired glucose tolerance (most of whom probably had metabolic syndrome). Also, numerous epidemiologic studies have shown a 30% to 50% decrease in the risk for developing coronary heart disease, as well as type 2 diabetes, with the maintenance of a physically active compared with a sedentary lifestyle.[262] It must be emphasized, however, that the incidence of diabetes in the treated patients with impaired glucose tolerance in these studies was still higher than in the general population,[61,63] suggesting that, to be maximally effective, lifestyle changes may have to be introduced even earlier. Whether lifestyle changes have a similar effect on coronary heart disease is less certain. However, in follow-up studies of patients in the US and Finnish diabetes prevention program who were insulin-resistant, diet and exercise diminished nontraditional risk factors for coronary heart disease, such as C-reactive protein and fibrinogen, as well as some of the more classic risk factors associated with metabolic syndrome.[263,264]

Drug Therapy

When recommended therapeutic goals are not achieved with diet and exercise, pharmacologic therapy is necessary. The recommendations of the AHA/NHLBI/ADA at different stages of metabolic syndrome, based on Framingham risk scores for developing ASCVD, have been presented elsewhere.[22,235] Suffice it to say, they vary with an individual's risk for developing coronary heart disease and cerebrovascular disease over given time intervals. Thus, in an individual already at risk for these disorders because of diabetes, the use of statins and other agents to diminish plasma cholesterol has a lower goal (LDL cholesterol <100 mg/dL) than in an individual with isolated hypercholesterolemia. Likewise, certain antihypertensive agents such as angiotensin-converting enzyme inhibitors[265] and fibric-acid derivatives[266] may be of special benefit in patients with type 2 diabetes or at high risk for developing it.

In patients with diabetes, metformin and TZDs have been routinely used because of their blood glucose-lowering actions and, in the case of the TZDs, their insulin-sensitizing effect (see Table 26.4). In regard to metformin's mechanism of action, it is well established that metformin decreases fasting plasma glucose and insulin concentrations through inhibition of hepatic gluconeogenesis.[269] Early studies suggested this might be related to its ability to activate AMPK in the liver[268]; however, recently this effect was attributed to inhibition by metformin of mitochondrial glycerophosphate dehydrogenase activity resulting in an increase in the cytosolic redox state and decreased conversion of lactate and glycerol to glucose.[269] To what extent metformin and other oral agents should be used as second-line therapy for metabolic syndrome in the absence of diabetes or impaired glucose tolerance is still a matter of debate. In 2004, an AHA/NHLBI/ADA conference on metabolic syndrome[261] concluded that "there is insufficient evidence to recommend these drugs for anything other than their glucose-lowering action at this time." On the other hand, as already noted, both metformin and TZDs have shown some efficacy in treating NAFLD and PCOS, and in the United Kingdom prospective diabetes study[270] chronic metformin therapy was associated with a decrease in new cardiovascular events in obese individuals with type 2 diabetes that was still evident 10 years after this initial finding.[271] Likewise, effects of metformin on diminishing the growth of cancers[272] and slowing the progression of Alzheimer disease have been described, as have activation of AMPK by metformin in endothelial cells[273] and human adipose tissue.[274,275]

The picture with respect to the TZDs is less clear. TZDs have shown efficacy equal to that of lifestyle change and better than that of metformin in diminishing progression from impaired glucose tolerance to overt diabetes,[61,65] and they have shown utility in treating NAFLD.[239] However, a controversial metaanalysis[276] concluded that the TZD rosiglitazone increases the incidence of myocardial infarction in patients with established type 2 diabetes. In contrast, in a second metaanalysis by the same group[277] and in a large prospective study,[278] a different TZD, pioglitazone, was found to cause a modest decrease in cardiovascular events and/or death due to myocardial infarction. Pioglitazone has also been demonstrated to decrease the progression of atherosclerosis and diminish plaque size in patients with type 2 diabetes.[279] In part based on these findings, a special panel of the Joint American and European Diabetes Associations recommended that rosiglitazone not be used for the therapy of type 2 diabetes.[280] Whether pioglitazone should be used for this purpose is also uncertain, because it appears to predispose patients to osteoporosis[281] and, in a small percentage of individuals, cancer of the bladder. As recently reviewed, these findings have led to a concentrated effort to develop new TZDs that do not have these effects.[282]

The role of statin therapy in patients with metabolic syndrome is somewhat clearer. A subgroup analysis of statin trials revealed that this class of agents reduces the risk for cardiovascular events in individuals with metabolic syndrome.[282] To what extent this is because of their apolipoprotein B–containing lipoproteins and/or their antiinflammatory action[187,283] is uncertain. Recently it has been demonstrated that treatment with rosuvastatin (for 1.9 years) reduces the incidence of major cardiovascular events by 50% in apparently healthy 60- to 70-year-old individuals, and that it does so independently of hyperlipidemia and other indices of metabolic syndrome and of plasma cholesterol.[187] Presumably, statins would have the same or an even greater effect in individuals with metabolic syndrome and evidence of inflammation; however, this remains to be proven. On the other hand, the finding that statins increase the incidence of type 2 diabetes in a small subgroup of patients has raised some questions about its use.[284] The NHLBI/AHA/ADA panel[261] recommended that cigarette smoking be discouraged in all individuals with metabolic syndrome. It also suggested that low-dose aspirin for primary prevention of coronary heart disease in patients with metabolic syndrome is promising,[282] as may be therapy with salsalate, an aspirin derivative, which, as noted earlier, also activates AMPK.[150] The subject of treatment of metabolic syndrome, based on the risk for coronary heart disease by Framingham criteria, has recently been reviewed.[22,285]

Special Considerations

The diagnosis and treatment of metabolic syndrome presents some special obstacles. With upwards of 50 million individuals with this diagnosis in the United States, it is a massive public health problem. In some individuals, diabetes, coronary heart disease, liver disease, and hypertension are already present, and in others, the central problem is how to prevent these disorders from occurring. Finally, there are many therapeutic options at our disposal; however, some, such as diet and exercise, are often difficult to utilize and maintain successfully, and others, such as drug therapy, are expensive, and in some populations (e.g., children and adolescents) they are untested and/or available data are conflicting. Also, as already noted, the potential side effects of some of these agents need to be considered.

The magnitude of the problem is such that the prevention of diseases associated with metabolic syndrome will almost certainly require governmental, societal, and individual change. In such an effort, a primary target will be the prevention of obesity and central adiposity through increasing physical activity and promoting healthy eating.[18] It has recently been suggested that, for children at risk for developing type 2 diabetes, school-based programs and governmental actions that focus on lifestyle will be required.[18] It is highly likely that similar programs will be required for adults.

With respect to drug therapy, we already have an array of agents that are at least partially successful in treating insulin resistance and other components of metabolic syndrome (e.g., the proinflammatory state) and diminishing diseases that can emanate from it, including type 2 diabetes and coronary heart disease. As we gain a better understanding of the pathogenesis of metabolic syndrome, it is likely that newer agents will be developed and that we will discover how to use currently available drugs (e.g., metformin, TZDs, and statins) or drugs derived from them more effectively.

KEY POINTS

- Lifestyle modifications, consisting of diet to induce weight loss and exercise, have been shown to diminish many of the abnormalities of metabolic syndrome and to prevent or delay progression from impaired glucose tolerance to type 2 diabetes in prospective studies. Because of this and their safety and low cost, diet and exercise are the first line of therapy for children and adolescents with metabolic syndrome and for adults without associated diseases. The role of metformin, "insulin-sensitizing" agents such as TZDs in individuals who are not hyperglycemic remains to be determined.

CHILDREN AND ADOLESCENTS

Recent studies indicate that the prevalence of metabolic syndrome is increasing dramatically in children and adolescents in parallel with the increase in obesity and type 2 diabetes. In adolescents 12 to 19 years of age in the National Health and Nutrition Examination Survey study (1988–1994), metabolic syndrome, diagnosed by ATP III criteria, was present in 4% of the total population, 6.8% of those classified as overweight (BMI 85th to 95th percentile), and 28% of those categorized as obese (BMI >95th percentile).[286] Furthermore, because the incidence of obesity until recently has been increasing in the years since these data were obtained, these are likely underestimates of its prevalence at the present time.

Where studied, metabolic syndrome in children and adolescents has been associated with insulin resistance, central adiposity, dyslipidemia, elevations in blood pressure, and increases in intramyocellular and intrahepatic lipids, much as in adults, although with different absolute measurements.[19,20] In addition, as in adults, the prevalence of NAFLD[240] and PCOS[68] are increased, as are plasma levels of the proinflammatory markers C-reactive protein and IL-6, and immunoassayable adiponectin in plasma is diminished.[20] Also, the prevalence of CVD in these individuals later in life may be increased.[287-289] Current treatment recommendations for children with type 2 diabetes, most of whom have metabolic syndrome, have been discussed critically by an International Diabetes Federation Consensus Workshop.[18]

LOW BIRTH WEIGHT INFANTS (EPIGENETIC CHANGES)

It has been known for some time that a low birth weight, independent of gestational age, predicts the development of type 2 diabetes, coronary heart disease, central obesity, and other aspects of metabolic syndrome in middle age in some individuals.[290,291] Recent reports suggest that the greatest risk is in infants with low birth weight who gain weight rapidly in childhood.[292] It has been suggested that an altered intrauterine environment (e.g., poor nutrition) could be responsible for the low birth weight in these children; however, the precise nature of these alterations is not known. Because of the long period between the malnutrition and the development of disorders, many years later it was suggested that epigenetic changes may be involved. This question was subsequently investigated in individuals prenatally exposed to food deprivation during the Dutch famine at the end of World War II (1944–1945). Six decades later, it was found that those individuals who were malnourished during the first trimester of pregnancy showed less DNA methylation of the maternally imprinted insulin-like growth factor 2 (*IGF2*) gene compared with their unexposed same-sex sibilings.[293] Interestingly, in middle age, these individuals were predisposed to obesity, altered lipid profiles, CVD, and accelerated cognitive aging.[294]

THE THRIFTY GENOTYPE AND THE INCREASING INCIDENCE OF METABOLIC SYNDROME

The recent increase in the prevalence of metabolic syndrome and type 2 diabetes has been attributed to the epidemic of obesity that began in the second half of the twentieth century and continues unabated. As reviewed elsewhere,[295] this is almost certainly a reflection of environmental factors, most notably the increased availability of food (and possibly the higher carbohydrate content of our diet over the past 50 years) and the decrease in physical activity that occurred in many industrialized societies during this time period.

In 1962, Neel[296] raised the question of why diabetes (type 2), which has adverse effects on health, persisted in humans during the course of evolution. He suggested that it could be related to the existence of a "thrifty gene" that predisposes individuals to obesity, and secondarily diabetes, but had survival value for our hunter-gatherer ancestors. More specifically, he proposed that in the feast-famine environment of early humans "individuals exceptionally efficient in the uptake and utilization of food and its storage as fat" would have had a selective advantage. Neel further suggested that, in our modern environment of calorie surplus, such a gene (or genes) that protected us from death when food sources were scarce may make us prone to obesity and diabetes (and metabolic syndrome).

Over the years, many candidate thrifty genes have been proposed, including *UCP2, UCP3,* and those encoding B_3-adrenergic receptors. Genes governing the AMPK/malonyl CoA fuel-sensing network, which has been linked to the regulation of both food intake[105,168,297] and energy expenditure,[106,111] have also been suggested. This is an attractive notion, because a decreased ability to oxidize fatty acids appears to be characteristic of preobese humans.[76,110] For the same reason, genes that regulate mitochondrial biogenesis also need to be considered.[7] Decreased mitochondrial content/activity, be it acquired or inherited, may promote obesity by two mechanisms. First, by decreasing daily energy expenditure, even by a small amount, it could lead to progressive weight gain. For instance, a 50-calorie/day reduction in energy expenditure in a typical adult, if not accompanied by a comparable decrease in food intake, would lead to a weight gain of approximately 5 lb/year. Second, a decrease in mitochondrial activity in skeletal muscle, by predisposing an individual to altered cellular lipid metabolism (as reflected by an increase in intramyocellular triglyceride), like alterations in the AMPK/malonyl CoA network,[75] can lead to insulin resistance and hyperinsulinemia.[118] The latter, in turn, could promote obesity by increasing lipogenesis in liver and adipose tissue and by inhibiting lipolysis until a new, more obese, steady state is achieved.

INTRODUCTION/OVERVIEW

Healthy food choices with portion control, as well as consistent exercise, are the mainstays of a healthy lifestyle and maintenance of a healthy weight. An imbalance of these factors can contribute to obesity with its associated diseases. Surgically-induced weight loss is the most potent form of weight loss intervention, particularly in individuals with class 2 and class 3 obesity, and can treat many obesity-associated diseases. The potential health benefits of surgically-induced weight loss include improved survival, improvement and remission of type 2 diabetes, and a reduced incidence of diabetes, cardiovascular disease, and cancers in women.

The epidemic of medically severe obesity coupled with the development and widespread utilization of less invasive laparoscopic techniques has led to a consistent increase in the annual number of bariatric operations performed, as well as the development of endoscopic bariatric interventions and together provide a multidisciplinary approach with escalating obesity interventions (Fig. 27.1).

We will begin by discussing the various bariatric operations and procedures, followed by discussion of the metabolic and physiologic consequences.

COMMONLY PERFORMED BARIATRIC OPERATIONS

With the development of endoscopic procedures for weight loss, it has become necessary to differentiate between bariatric surgical *operations* and bariatric endoscopic *procedures*. We will begin by discussing the anatomy and general mechanisms of the operations most commonly performed for weight management (Fig. 27.2).

The mechanisms behind bariatric operations have components of restriction, malabsorption, and neurohormonal changes. All operations have a varying combination of these three components as their mechanism, resulting in a unique anatomy and physiology that can affect caloric intake, nutrient handling, and nutrient sensing. These changes likely influence each operation's unique outcome, as discussed later in this chapter. Although much has been learned regarding these mechanisms, much remains to be understood.

All these operations are performed laparoscopically, which benefits the patient because there are fewer wound complications, less pain, and earlier return to activities compared with open operations.[1,2] Outcomes after bariatric surgery are categorized into the effect on weight and the effect on weight-related comorbid disease, particularly metabolic disease. Potential adverse effects to be considered include nutritional complications.

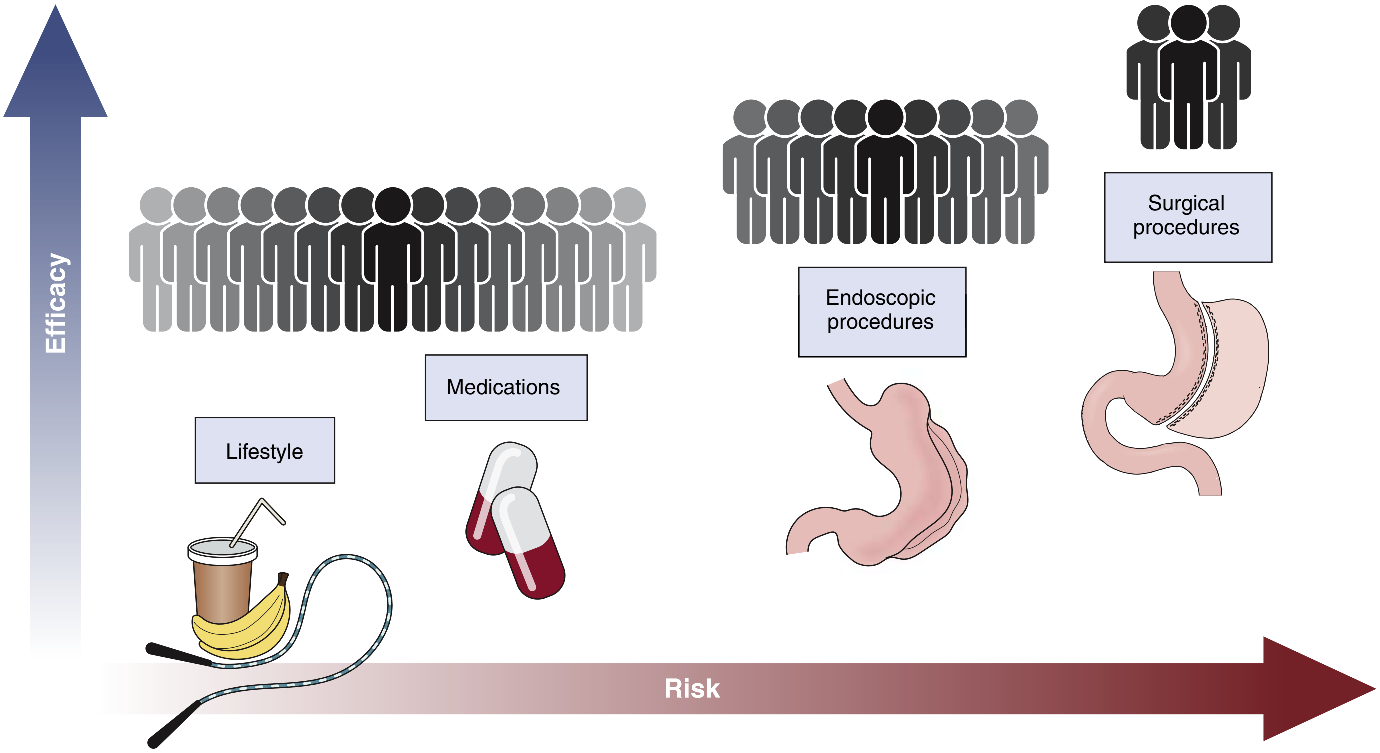

Figure 27.1 Escalating interventions in the treatment of obesity.

Vertical Sleeve Gastrectomy

Sleeve gastrectomy (SG) is currently the most commonly performed bariatric procedure in the United States and worldwide, comprising approximately 65% of all bariatric operations in the United States. Its rapid adoption can be attributed to it being a less technically demanding operation that has very good weight loss, as well as improvement of obesity-related comorbid diseases. Although the SG is a promising operation for treating obesity, the development of gastroesophageal reflux disease (GERD) postoperatively and long-term weight regain are growing concerns[3] and thus, as with any bariatric operation, careful patient selection is of paramount importance.

The SG is a restrictive operation with a neurohormonal component.[4] The restrictive component occurs by way of an approximately 75% to 80% reduction of the gastric volume via resection of the gastric greater curvature including the gastric fundus (see Fig. 27.2B). Its neurohormonal effects are not completely understood but are thought to be the result of the reduction of ghrelin-producing oxyntic gland endocrine P/D1 cells[5-7] located in the gastric fundus and parietal cells of the gastric greater curvature. A prospective, double-blind study that compared Roux-en-Y gastric bypass (RYGB) and laparoscopic SG demonstrated significant postprandial suppression of ghrelin after SG and no change after RYGB. Appetite reduction and excess weight loss (EWL) were greater after SG, suggesting an association with the suppression of ghrelin levels. In the same study, peptide YY (PYY) levels were increased similarly after either operation.[8]

An increase in gastric emptying with upregulation of glucagon-like peptide 1 (GLP-1) has also been proposed as a mechanism for the effects of SG. However, the evidence is mixed, which may be secondary to variations in surgical technique.

SG is a very safe operation, with a 30-day mortality rate of 0.2% to 0.5%.[9,10]

Roux-en-Y Gastric Bypass

Although the SG is currently the most commonly performed bariatric operation in the United States, in many ways the RYGB is still considered the gold standard bariatric operation. It has a solid track record of efficacy, durability, and safety over more than 20 years of follow-up, which the SG lacks. Although its effects are mostly due to restriction and neurohormonal changes, it also has a small malabsorptive component.

The RYGB creates a small approximately 15- to 30-mL gastric pouch that is constructed by dividing the upper aspect of the stomach, and this small pouch is then attached to a 75-cm to 150-cm jejunal Roux limb (see Fig. 27.2C). The so-called "biliopancreatic limb" is typically 40 cm to 100 cm in length and carries bile and digestive enzymes from the duodenum and from the remaining portion of the stomach (gastric remnant). The result of this anatomic configuration is that the ingested food and digestive juices are separated for the length of the Roux limb, after which they enter a long common channel of small bowel (the remainder of the jejunum and the entire ileum), where mixing of food with bile and digestive enzymes occurs. This anatomy results in the ingested food bypassing the majority of the stomach, the entire duodenum, and the first portion of the jejunum. In general, the relatively small length of bypassed intestine (roughly 30%) is not enough to cause protein-calorie malabsorption. However, it does impact the absorption of some micro- and macronutrients, and specifically calcium, iron, vitamin B12, and vitamin D.

The mechanism of action leading to weight loss and comorbidity improvement is multifactorial. Like the SG, the RYGB is mainly a restrictive procedure with additional neurohormonal effects. However, unlike the SG, bypass of the duodenum and proximal jejunum as well as rapid delivery of chime to the distal small bowel are thought to be important mechanisms resulting in alteration in of the entero-endocrine axis. The changes observed in gut peptides caused by rapid delivery of nutrients to the jejunum (glucose-dependent insulinotropic polypeptide and GLP-1) after bypass of the duodenum may be an important long-term mechanism for durable weight loss and comorbidity remittance.[11]

Figure 27.2 **A,** Adjustable gastric band. A silicone band is looped around the proximal stomach to create a 15- to 20-mL pouch with an adjustable outlet. The stomach is wrapped around the band anteriorly to prevent the band from slipping out of position. The band consists of a rigid outer ring and an inner inflatable balloon reservoir connected by tubing to a subcutaneous port that can be accessed through the skin to adjust the tightness. **B,** Sleeve gastrectomy. A narrow gastric sleeve is created by stapling the stomach vertically. The fundus and greater curve of the stomach are surgically removed. **C,** Roux-en-Y gastric bypass (RYGB). A small gastric pouch (15–30 mL) is created by division of the upper stomach connected to a 100- to 150-cm limb of jejunum called the Roux limb. The small gastric pouch results in restriction of food intake. **D,** Biliopancreatic diversion with duodenal switch (BPD-DS). To avoid acid reflux, marginal ulcers, and dumping syndrome by maintaining the pylorus, the operation was modified with the pouch based on the lesser curve of the stomach and an anastomosis at the first portion of the duodenum. **E,** Single anastomosis duodenal ileal bypass with sleeve (SADI-S). A variation of the BPD-DS in which a single anastomosis is constructed 250–300 cm proximal to the ileocecal valve.

Gastric bypass is a very safe and extremely effective bariatric operation. The associated 30-day mortality is 0.2%, incidence of unplanned intensive care unit admissions is 1.3%, and incidence of 30-day reoperations is 2.5%.[12] This low perioperative risk is accompanied by a nearly 30% to 35% total body weight loss (TBWL). The weight loss outcomes are sometimes reported as "excess body weight loss," meaning the patient has lost an amount of weight above "ideal" body weight, which for RYGB would be approximately 70% excess body weight loss. In addition to the highly significant weight loss, there is a high rate of improvement or remission of obesity-related comorbidities,[13] which makes the RYGB a good choice for treatment of obesity and its complications.

Biliopancreatic Diversion with Duodenal Switch

Biliopancreatic diversion with duodenal switch (BPD-DS) is the most powerful bariatric procedure in terms of weight loss and the treatment of diabetes and other obesity-related comorbidities. It is a technically challenging operation and has a higher incidence of complications compared with RYGB and SG. Primary BPD-DS represents less than 1% of all bariatric operations in the Unites States [https://asmbs.org/resources/estimate-of-bariatric-surgery-numbers]. However, BPD-DS is beginning to gain popularity as a revision operation, especially in the setting of weight regain after SG.[14]

The effects of the BPD-DS can be attributed to components of restriction, malabsorption, and neurohormonal changes and, compared with the SG and RYGB, is the only bariatric operation that employs true protein-calorie malabsorption as a mechanism for weight loss (see Fig. 27.1D). The BPD-DS combines a modest SG with an extensive bypass of the small bowel while preserving the pylorus. Preservation of the pylorus theoretically decreases the risk of developing dumping syndrome and reactive hypoglycemia.[15,16] The BPD-DS anatomy is a combination of restriction (vertical SG) and malabsorption (extensive intestinal bypass). The malabsorptive component is profound, and its contribution is what creates the most amount of weight loss. The intestinal bypass has a metabolic effect thought to be due to early exposure of nutrients to the ileum leading to increased levels of PYY and GLP-1.[17] The length of the intervening bowel between the alimentary limb-biliopancreatic limb anastomosis and the cecum, termed the "common channel," is the main determinant of the degree of malabsorption. As the length of the common channel becomes shorter, the malabsorptive power of the operation increases, and with it the potential weight loss. However, the risks of the adverse effects associated with aggressive malabsorption also increase and can lead to severe macro- and micronutrient deficiencies, including sometimes fatal protein-calorie malnutrition.

The BPD-DS is the most effective bariatric operation currently performed, producing the most weight loss and the best rates of diabetes remission.[18-20] However, due mainly to its impact on nutrition, it is associated with higher morbidity compared with other procedures, with a reported 8% to 11% overall complication risk.[21] BPD-DS may be best reserved for patients with body mass index (BMI) greater than 50 kg/m^2 or as a revision procedure for patients with inadequate weight loss after SG. Because of the potential for malnutrition after BPD-DS, this operation should be avoided in patients who are unlikely to be compliant with postoperative dietary guidelines and nutrition supplements. In our experience, those with a heavy burden of mental health issues, lack of stability in their personal lives, and a poor social support system, as well as those who exhibit dubious compliance preoperatively, are not considered candidates in our program.

Single Anastomosis Duodenal Ileostomy Bypass With Sleeve

The single anastomosis duodenal ileostomy bypass with sleeve (SADI-S) is a modification of the classic BPD-DS and was initially described by Torres over 10 years ago.[22] The SG portion of the operation is the same. However, rather than a Roux-en-Y configuration of the bypassed small bowel, the SADI-S has a loop configuration with one anastomosis between the proximal duodenum and the ileum constructed 250 to 300 cm proximal to the ileocecal valve, which eliminates the biliopancreatic diversion portion (see Fig. 27.2E). This operation has recently been endorsed by the American Society for Metabolic and Bariatric Surgery (ASMBS) as effective and safe. It can be offered as a primary bariatric operation or for revision of SG in the setting of weight regain. Early studies have suggested that weight loss and comorbidity outcomes are similar to those of the BPD-DS. One retrospective study demonstrated 85.7% EWL at 4 years postoperatively, with 97.6% patients being able to maintain hemoglobin A1c (HbA1c) less than 6% (with or without diabetic medications).[23] Other retrospective studies have shown more weight loss in BPD-DS patients compared with SADI-S patients.[24] The postulated advantages over the traditional BPD-DS include a lower risk of internal hernias and lower risk of malnutrition and diarrhea.[25]

Laparoscopic Adjustable Gastric Banding

The adjustable gastric band (AGB) is a Silastic device that is comprised of a band with an inner balloon attached to tubing that leads to a subcutaneous port (see Fig. 27.2A). Its relatively simple concept, straightforward surgical procedure, low mortality, and reversibility drove its initial popularity to the point where it was the most popular weight loss operation in 2007. However, it has lost favor due to poor long-term weight loss and unacceptable long-term complication and reoperation rates, as well as the emergence of the SG as the restrictive operation of choice. The AGB currently comprises approximately 1% of all bariatric operations.

KEY POINTS

- The vertical sleeve gastrectomy (SG), a restrictive operation with a neurohormonal component, is currently the most commonly performed bariatric operation in the United States.
- The Roux-en-Y gastric bypass provides restriction as its main mechanism, coupled with a neurohormonal component. The limited malabsorptive component is not designed to provide protein-calorie malabsorption as a weight loss mechanism.
- The biliopancreatic diversion with duodenal switch and single anastomosis duodenal ileostomy with sleeve gastrectomy are primarily malabsorptive operations and can result in profound protein-calorie malabsorption. The SG portion of these operations also provides restriction, and there is an associated robust neurohormonal component.
- The adjustable gastric band is a purely restrictive operation that currently comprises less than 2% of the bariatric operations being performed.

Endoscopic Bariatric and Metabolic Therapies

The burden of obesity is compounded by an insufficient treatment arsenal. Behavioral changes are thwarted by low durability and patient compliance.[26,27] Pharmacologic therapies are associated with significant cost and potential adverse events, require lifelong compliance to maintain response, and, given their targeted nature of redundant evolutionary pathways defending body weight, are often inflicted with weight recidivism and attenuation of response.[28,29] Bariatric surgery, while associated with significant and sustained weight loss, is limited by its invasiveness, expense, long-term risks, and patient acceptance.[30-32] These barriers have prevented bariatric surgeries from reaching more than 2% of eligible patients, with the vast majority of patients with mild to moderate obesity not qualifying for surgery.[32,33] Furthermore, obesity equally inflicts younger patients, who will likely outlive the durability of bariatric surgery and require additional revision surgery, which significantly compounds the short- and long-term risks and cost.[34,35] This landscape has provided an opportunity for

minimally-invasive and anatomy-preserving endoscopic bariatric and metabolic therapies (EBMTs) to address the gaps in obesity care and increase access to effective therapies capable of producing significant weight loss and improvement in excess adiposity–related comorbidities.[36] Recognizing the noncurable, chronic, relapsing nature of obesity, an evolving management strategy pivoting on an intensive weight loss intervention utilizing EBMT for those with moderate forms of the disease is needed. The goal of such a strategy is to produce enough upfront weight loss that the patients will engage in lifelong weight stabilization and reintensification efforts, similar to any other chronic disease, where interventions are layered and sequenced for effective disease management.[37]

EBMTs are generally considered in patients who do not qualify for or who wish to pursue bariatric surgery, especially in those with class 1–2 obesity (BMI 30–40 kg/m^2) who have previously failed to lose weight using lifestyle methods. Furthermore, EBMTs can be utilized as a bridge to definitive bariatric surgery in patient with very high BMIs and prohibitive surgical risk.[38-40] Other indications include:

1. Prior to organ transplantation, allowing pretransplant candidates to meet transplant eligibility.[41-43]
2. Weight reduction prior to orthopedic procedures and for infertility treatment.[44]
3. For management of obesity-related comorbidities such as nonalcoholic steatohepatitis and type 2 diabetes.[45-48]

EBMT approaches are thought to target peripheral and central gastrointestinal pathways implicated in the regulation of energy intake and can be divided based on their anatomic manipulation into gastric or small intestinal interventions (Fig. 27.3).[49]

1. Gastric interventions include space-occupying devices that most commonly take the form of temporarily placed prostheses (intragastric balloons [IGBs]). The TransPyloric Shuttle (BAROnova Inc, Goleta, CA) intermittently seals the pyloric channel and delays gastric emptying in the fed state to induce early satiation and prolonged satiety. The Full Sense Device (BFKW, Grand Rapids, MI) is a modified, fully covered gastroesophageal stent with a cylindrical esophageal component and a gastric disc connected by struts that is thought to induce weight loss by exerting constant gentle, pressure on the gastric cardia, thereby triggering afferent vagal signaling to the central nervous system and a sensation of fullness. Additional approaches that target the stomach include gastric remodeling techniques that reduce the gastric reservoir by endoscopically creating a tubular sleeve along the greater curvature of the stomach through transoral suturing (Overstitch, Apollo Endosurgery, Austin, TX) or plication (POSE, USGI Medical, San Clemente, CA) and aspiration therapy that allows patients with obesity to dispose of a portion of their ingested meal via a specially designed percutaneous gastrostomy tube, known as the A-Tube (Aspire Bariatrics, King of Prussia, PA).
2. Small bowel interventions: it has been hypothesized that the proximal small intestine plays a role in the pathogenesis of metabolic disease, resulting in insulin resistance and chronic inflammation. The pathways that have been proposed include alteration of neurohormonal signaling, changes in the gut microbiome and mucosal barrier function, and activation of innate immune reactions caused by an excess of free fatty acids, bacterial lipopolysaccharides, chemokines, and cytokines.[50] The approaches that have been designed to address these pathways include the exclusion of the proximal small intestines by impermeable polymer duodenojejunal bypass liners (EndoBarrier, GI Dynamics, Lexington, MA; Metamodix, Minneapolis, MN) and ablative duodenal resurfacing techniques that regenerate the proximal small intestinal mucosal barrier by thermal or nonthermal ablation methods (Fractyl Laboratories, Cambridge, MA). Some of these therapies have shown promise in the

management of obesity and metabolic disease. Another theory is that primary and secondary bile acid concentrations and composition in the intestinal, portal, and systemic circulation play roles in insulin secretion and sensitivity, metabolic rate, liver lipogenesis and inflammation, and liver fibrosis progression through FXR/fibroblast growth factor (FGF)15 and FGF19/TGR5 signaling.[51] In hopes of favorably altering bile acid profiles, endoscopic treatments have been developed that deploy self-assembling magnets (GI Windows, Boston, MA) to create a dual-path enteral bypass between the proximal jejunum or duodenum and ileum in order to partially divert bile to the terminal ileum.

EVOLVING EVIDENCE PROFILE FOR THE USE OF ENDOSCOPIC BARIATRIC AND METABOLIC THERAPIES IN CLINICAL PRACTICE

Space-Occupying Devices

Space-occupying devices can be divided into balloon and nonballoon devices. At present time of this publication, there are four US Food and Drug Administration (FDA)-approved space-occupying devices (ReShape Duo, Orbera, Obalon, and the Transpyloric Shuttle). The ReShape Duo balloon is no longer being marketed. Two additional IGBs (Spatz3 and Elipse) have completed pivotal US regulatory trials and are awaiting approval in the United States.

1. **Orbera** is the most-studied IGB for obesity. The device is a single fluid-filled spherical balloon system that requires endoscopy to confirm placement. Once placed in the stomach, the balloon is filled with 450 to 700 mL of saline with optional methylene blue to detect spontaneous deflation. At 6 months, the balloon requires endoscopic removal. Balloon intolerance was reported to be 7.5%.[52] A prior metaanalysis of 55 studies that included over 6500 Orbera IGB placements demonstrated a pooled estimate of 13.2% TBWL at 6 months and 11.3% at 12 months.[53] In a pivotal US multicenter randomized controlled clinical trial, investigators compared subjects (n = 125) who received 6 months of balloon therapy plus lifestyle intervention with those who received lifestyle intervention alone (n = 130). At time of removal (6 months), the %TBWL in the Orbera group (n = 116) was 10.2 ± 6.6% versus 3.3 ± 5% in the control group (n = 99). At 12 months, patients in the balloon arm maintained more than 70% of their weight lost at 6 months.[52] In a metaanalysis of over 65 studies, accommodative symptoms after placement, such as abdominal pain and nausea, were frequent side effects, occurring in 29% to 34% of patients, but these symptoms mostly dissipated after a few days of therapy. Serious side effects such as migration and gastric perforation were 1.4% and 0.1%, with 50% of the perforations occurring in those with prior gastric surgery, which is a contraindication for placement in the United States.[53,54]
2. The **Obalon** balloon is a gas-filled balloon system packaged within a gelatin capsule. The capsule contains a self-sealing valve that is connected to a thin catheter extending from the stomach to the mouth when the capsule is ingested. Capsule entry into the stomach is verified by fluoroscopy or a percutaneous locating device that does not use radiation; upon entry into the stomach, the gelatin dissolves, freeing the balloon. The catheter is then used to inflate the balloon with a nitrogen gas mixture. The inflated balloon detaches from the catheter and remains in place until it is removed endoscopically after 12 to 26 weeks. Up to three capsules can be swallowed during the same session, or preferably sequentially throughout therapy as weight loss plateaus. In a US pivotal multicenter randomized sham-controlled clinical trial, investigators compared 198 patients receiving up to three consecutive balloon capsules plus lifestyle intervention to 189 patients receiving sham capsules in addition to lifestyle intervention. %TBWL in the IGB balloon arm was 6.6 ± 5.1% at 6 months from the first swallowed capsule compared with 3.4 ± 5.0% in the control group. The safety profile of the Obalon IGB system is favorable. In the pivotal trial, no unanticipated adverse device events occurred, and only one serious adverse event occurred, which was a gastric ulcer in the setting of nonsteroidal antiinflammatory medication use. Transient mild to moderate nausea and abdominal pain were common and self-limited, with the vast majority of patients completing therapy.[55]
3. **Spatz** is an adjustable fluid-filled IGB placed endoscopically. The balloon has an extractable thin, flexible tube that allows for endoscopic volume adjustment while the balloon is in place. The balloon volume may be decreased to improve tolerability or increased to aid in increased weight loss. Prior generations of the Spatz adjustable balloon resulted in up to 20% TBWL at 12 months but had device-related complications.[56] The new-generation device overcomes these design flaws and is approved for 12-month placement outside of the United States. A US multicenter pivotal trial randomized 288 participants (187 IGB and 101 open-label control). At 32 weeks the IGB cohort achieved 14.9 ± 7.2% TBWL compared with 3.6 ± 5.8% in the control group, for a difference of 11.3%([97.5% lower confidence bound 9.1%). The serious adverse events rate was 5.3%, and these events were mostly related to persistent accommodative gastrointestinal symptoms.[57] The device is currently awaiting regulatory approval.
4. The **Elipse** balloon is the first procedureless IGB that does not require an endoscopy to place or to remove. It is administered by swallowing a capsule with an attached microcatheter through which the balloon is filled once the balloon capsule is confirmed to be within the stomach on an abdominal x-ray. The balloon subsequently self-deflates after degradation of its valve mechanism, permitting release of balloon contents and the entire device and contents are expected to pass through the gastrointestinal tract and be excreted spontaneously in the stool approximately 4 months after administration. In a systematic review and metaanalysis including 2013 unique patients with mild to moderate obesity, the pooled early removal rate was 2.3% (95% confidence interval [CI]: 1.1%–3.5%; I2 31%) and pooled %TBWL after completion of treatment (4–6 months) was 12.8% (95% CI: 11.6%–13.9%; I2 83%) and at 12 months was 10.9% (95% CI: 5.0%–16.9%, I2 98%). Three patients in this study developed small bowel obstruction with balloon exit, and one patient had gastric perforation requiring surgery.[58] A pivotal US regulatory multicenter randomized sham-controlled trial has concluded, and the balloon is awaiting regulatory approval.
5. The **TransPyloric Shuttle** consists of a large spherical bulb attached to a smaller cylindrical bulb with a flexible tether. The device is delivered and removed through an overtube with endoscopic guidance. The large bulb remains in the stomach, while the smaller bulb can traverse to the duodenum during peristalsis. It creates an intermittent gastric outlet obstruction to delay the gastric emptying of ingested meals and induce satiety. The FDA approved this device in April 2019 for use in patients with a BMI of 30 to 40 kg/m^2 for 12 months. A US pivotal multicenter randomized double-blinded sham-controlled trial (ENDobesity II) involving 270 patients (181 TransPyloric Shuttle and 89 sham) led to this approval. At 12 months, the %TBWL was 9.5% for the TransPyloric Shuttle group, compared with 2.8% in the sham group. The incidence of serious adverse events in the TransPyloric Shuttle group was 2.8%, in which one patient experienced esophageal rupture that occurred

during an unsuccessful delivery attempt. The early removal rate due to adverse events was14.8%.(https://www.accessdata.fda.gov/cdrh_docs/pdf18/P180024B.pdf)

Gastric Remodeling Techniques

Endoscopic Sleeve Gastroplasty. Endoscopic sleeve gastroplasty (ESG) is an incisionless gastric volume reduction technique that creates a restrictive endoscopic sleeve. This endoscopic sleeve is achieved using a commercially available full-thickness suturing device (OverStitch; Apollo EndoSurgery, Austin, TX, USA) by placing a series of triangular full-thickness sutures through the gastric wall along the greater curvature of the stomach from the prepyloric antrum to the gastroesophageal junction, leaving a small pouch in the fundus (Fig. 27.4A).[59] In a systematic review and metaanalysis of eight studies involving 1776 patients with a follow-up of up to 2 years, the body weight loss at 6, 12, and 18 to 24 months was 15.1%, 16.5%, and 17.2%, respectively. The reported rate of serious adverse events was 2.2%.[60] Although most studies evaluated the impact of ESG on body weight, two evaluated its association with important metabolic parameters.[61,62] Sharaiha and colleagues observed a significant improvement in HbA1c, systolic blood pressure, triglycerides, and alanine aminotransferase 12 months post-ESG.[61] In another study, all patients with hypertension and 76.5% of patients with early type 2 diabetes mellitus achieved remission of these entities.[62] Limited longer-term studies have reported outcomes beyond 1 year.[63] However, beyond sustained weight loss, the postprocedural anatomy has not been routinely assessed beyond the immediate postprocedural phase. It is likely that considerable variability may be present, as the techniques, suture patterns, and follow-up protocols continue to evolve.

Primary Obesity Surgery Endoluminal. In its first iteration, primary obesity surgery endoluminal (POSE) used a peroral incisionless operating platform (USGI Medical, San Clemente, CA) to place transmural tissue anchor plications that reduce accommodation of the gastric fundus. Three additional plications are placed in the distal gastric body to delay gastric emptying (see Fig. 27.4B). POSE has been associated with both improved satiety, indicating a gut neurohormonal response.[64] A pivotal US multicenter randomized blinded clinical trial that compared 221 patients receiving POSE in addition to a low-intensity lifestyle intervention for 12 months with 111 patients receiving lifestyle intervention alone failed to meet its primary efficacy endpoints, with a reported weight loss at 12 months for the POSE group of 5 ± 7% compared with 1.4% ± 5.6% in the control group.[65]

An alternative plication method, POSE2.0, where plications are placed in the gastric body between the gastroesophageal junction and level of the incisura, with none placed in the fundus, thereby generating a small food reservoir in the fundus with a tubular configuration of the remainder of the stomach, is being investigated, with encouraging early results (see Fig. 27.4C).[66]

Aspiration Therapy

Aspiration therapy (AT) is another endoscopic treatment approach involving partial disposal of an ingested meal to reduce overall caloric intake through a modified percutaneous endoscopic gastrostomy (PEG) tube. This device is FDA-approved for use in the United States in patients with a BMI between 35 and 55 kg/m^2, a higher BMI range than for IGBs, for up to 5 years. It requires endoscopic placement and removal, unlike standard PEG tubes. The AT process uses a specifically designed percutaneous gastrostomy tube (A-Tube, Aspire Bariatrics, King of Prussia, PA) made of silicone. The tube is inserted in a similar fashion as standard PEG tubes. After 2 weeks, the A-tube is shortened to the level of the skin, and the skin port is attached. The skin port allows attachment to the aspiration device, which fits in a small zippered bag. Once the device is connected to the skin port, a water reservoir flushes tap water into the stomach to facilitate disposal of food. Patients are instructed to perform aspiration approximately 20 minutes after ingesting a meal, removing and discarding approximately one third of the meal. The process takes approximately 10 to 15 minutes to complete. The device has a built-in counter that locks the device to avoid overuse. In a US pivotal multicenter randomized controlled trial, 111 subjects underwent AT with lifestyle intervention for 12 months compared with 60 subjects who underwent lifestyle intervention alone. At 12 months, %TBWL for those who completed AT (n = 82) was 14.2% ± 9.8% compared with 4.9% ± 7% in the control group (n = 31). Because aspiration removes around 30% of ingested calories, it is estimated that AT accounts for 80% of the reported weight loss. AT requires patients to chew food thoroughly and eat slower, potentially leading to new eating behaviors. As far as safety, the adverse events included stoma granulation tissue (40.5%), stoma infection (14.4%), peritonitis (0.9%), and gastric ulcer (0.9%). Careful review of disordered eating behavior questionnaires found no evidence of worsening eating behaviors with therapy.[67]

Small Bowel Intervention

Duodenal-Jejunal Bypass Liner. The Endobarrier (GI Dynamics, Lexington, MA) is a 65-cm-long Teflon-coated duodenal jejunal bypass sleeve. It is anchored at the duodenal bulb by an anchoring crown and terminates at the proximal jejunum, allowing ingested nutrients to bypass the duodenum to the jejunum, thereby altering proximal duodenal interaction with ingested nutrients and subsequent

gut hormonal and enteric nervous system response. This device is placed and removed endoscopically and remains in the small intestine for 12 months. A US pivotal multicenter randomized sham-controlled trial (the ENDO trial) was terminated early after enrollment of 325 of 500 patients because of a 3.5% incidence of hepatic abscess. All were managed conservatively, but this was outside the predefined adverse event rate. An analysis of published trials of this device identified two studies that included a sham control arm with a total of 77 volunteers who received treatment for 12–24 weeks. The analysis was specifically aimed at assessing the effects of this approach on T2DM outcomes; for these two trials there was not a significant improvement in HbA1c between intervention and control studies. A redesigned clinical trial of the same device with a modified protocol designed to reduce the likelihood of adverse events has been approved by the FDA to begin enrolling patients. Furthermore, a newer atraumatic bypass liner system is being developed.

Duodenal Mucosal Resurfacing. Intestinal adaptation to excess caloric intake and states of metabolic disease has been hypothesized and is illustrated in Fig. 27.5.[50,68,69] These pathophysiologic adaptations have been targeted by endoscopic technologies capable of resurfacing the mucosal layer of the duodenum in an attempt to reset abnormal metabolic signaling and improve insulin resistance. Duodenal mucosal resurfacing (DMR; Fractyl, Lexington, MA), or the Revita procedure, is an endoscopic procedure that involves circumferential hydrothermal ablation of the duodenal mucosa. This procedure is primarily aimed at glycemic control. Though the precise mechanism is not yet defined, it is hypothesized that DMR induces remodeling of the diseased duodenum with an overgrowth of enteroendocrine cells and dysregulated secretion of gastrointestinal hormones, which have been observed in patients with diabetes. The first human study of 39 patients with type 2 diabetes demonstrated a 1.2% reduction of HbA1c and a 2.5-kg weight reduction at 6 months. A longer segment ablation resulted in more potent glycemic control. Three patients developed duodenal stenosis, which was successfully treated with endoscopic dilation.[70] In a double-blind, randomized controlled trial (56 DMR, 52 sham) of patients with poor glycemic control despite greater than or equal to one stable oral antidiabetic medications with 24 weeks' follow-up, the median HbA1c decreased by 10.4 mmol/mol in the DMR group versus 7.1 mmol/mol in sham group ($P = 0.147$). Because of the heterogeneity between the two cohorts participating in the trial (European vs. Brazilian) the groups were analyzed separately, as prespecified in the statistical analysis plan. In the European modified intention to treat cohort (39 DMR, 37 sham) the median HbA1c change was –6.6 mmol/mol versus –3.3 mmol/mol post-sham ($P = 0.03$). The Brazilian cohort showed a statistically nonsignificant trend towards DMR benefit in HbA1c. Patients with high baseline fasting plasma glucose, greater than or equal to 10 mmol/L, had significantly greater reductions in HbA1c post-DMR versus sham ($P = 0.002$). One jejunal perforation was observed in this study requiring surgical repair.[47] A US multicenter randomized sham-controlled trial of hydrothermal ablation is underway. A newer ablation technique, utilizing electroporation in hopes of reducing serious adverse events and to enable safe re-treatment of the duodenum, is currently in early human trials.

Incisionless Magnetic Anastomosis System. The Incisionless Magnetic Anastomosis System (GI Windows, West Bridgewater, MA) consists of two self-assembling magnets that are deployed, one each in the proximal jejunum by enteroscopy and in the ileum by colonoscopy, with ileoscopy creating jejunoileal anastomosis, which results in partial jejunoileal bypass. The coupled magnets then pass spontaneously after a week. The first human proof-of-concept study involving 10 patients demonstrated a %TBWL of 14.6% and a significant reduction of HbA1c of 1.9% at 12 months utilizing laparoscopic assistance and monitoring. All anastomoses were patent at a 12-month follow-up.[71]

Special Considerations and Future Directions. The magnitude and duration of weight loss varies by EBMT device and technique. Therefore, EBMTs should be administered with the support of a comprehensive team of primary care providers, gastroenterologists, nutritionists, dieticians, and behavioral therapy professionals. Moving forward, personalized EBMTs targeting clinical phenotype and responders' profiles will be imperative. The sequential and tandem use of EBMTs in conjunction with antiobesity pharmacotherapy and comprehensive lifestyle interventions is an ongoing area of research, which may yield a robust and durable weight loss response, achieving a lasting effect on obesity and its comorbidities. In a proof-of-concept propensity score-matched study of 52 patients, those receiving endoscopic sleeve gastroplasty with liraglutide achieved 25% TBWL at 12 months (7 months after the initiation of liraglutide) compared with 21% in the ESG-only group.[72]

KEY POINTS

- Endoscopic bariatric and metabolic therapies (EBMT) are minimally invasive peroral management options that could augment the treatment spectrum for obesity and metabolic disease.
- EBMTs are generally considered in patients who do not qualify for or wish to pursue bariatric surgery, especially in those with class 1–2 obesity who have previously failed to lose weight using lifestyle methods.
- EBMTs include gastric space–occupying devices, gastric remodeling techniques, and small bowel interventions targeting metabolic pathways.
- EBMTs should be administered with the support of a comprehensive multidisciplinary team. The sequential and tandem use of EBMTs in conjunction with antiobesity pharmacotherapy and comprehensive lifestyle interventions is an ongoing area of research.

Eligibility for Bariatric Operations and Procedures

According to the current National Heart, Lung, and Blood Institute guidelines, candidates for bariatric surgery in the United States include patients with a BMI greater than 40 kg/m^2 or with a BMI of 35 to 39.9 kg/m^2 and one or more obesity-associated comorbidity (type 2 diabetes, cardiovascular disease, sleep apnea, dyslipidemia, hypertension, GERD, or osteoarthritis).[72a] These indications, which were established more than 25 years ago, may expand as more societies adopt this safe and durable weight loss option. In 2018, the ASMBS published a statement on the role of metabolic surgery in class 1 obesity. The issued statement supported lowering the BMI cutoff of 35 kg/m^2 to 30 kg/m^2 in consideration of the high-quality supporting data available.[73] At the very least, prospective patients must undergo a thorough preoperative evaluation by a bariatric surgeon, a dietician, and a psychologist. An endocrinologist's expertise is often necessary to assist in managing the metabolic complications of obesity. This multidisciplinary approach ensures consideration of the "whole patient," thus leading to favorable and long-lasting outcomes that are not solely dependent on behavioral changes induced by the operation.

KEY POINTS

- To be eligible for bariatric surgery or endoscopic bariatric procedure, patients must have a body mass index (BMI) >40 kg/m^2 or a BMI of 35–39.9 kg/m^2 and one or more obesity-associated comorbidity (type 2 diabetes, cardiovascular disease, sleep apnea, dyslipidemia, hypertension, gastroesophageal reflux disease, or osteoarthritis).
- There is mounting evidence supporting the application of bariatric operations and procedures for class 1 obesity (BMI 30.0–34.9 kg/m^2), particularly for patients in this weight class with type 2 diabetes mellitus.

Assessing Outcomes after Bariatric Interventions

The two main outcomes important in determining the success or failure of bariatric operations and procedures are: 1) weight loss and 2) comorbidity resolution. Many previous bariatric surgery studies measured outcomes as percent EWL, which is defined as the percent change from excess to ideal body weight. However, %TBWL is currently preferable, because this standardization is more easily comparable to the medical literature. %TBWL has the lowest variation coefficient and best describes weight loss changes over time for patients in different weight categories.[56,74] However, the data obtained from %TBWL may not accurately reflect the clinical benefit. For example, someone with greater excess weight will need to lose more weight to achieve the clinical benefits. For this reason, %EWL is sometimes preferred.

Weight loss is greatest after BPD-DS, and is generally in the range of %TBBL 30% to 40%, %EWL 70% to 90%, followed by RYGB (%TBL 28%–32%, %EWL 65%–80%) and SG (%TBL 25%–32%, %EBL 50%–65%). Recent randomized studies comparing the RYGB with the SG have demonstrated equivalent weight loss at 5 years.[75,76] However, it is generally believed that the RYGB results in superior weight loss compared with the SG over the long term. It should be remembered that weight loss outcomes depend on multiple factors, perhaps most importantly long-term compliance to behavioral modifications, resulting in variable outcomes. Generally, the operations with the greatest weight loss also carry the greatest risk for surgical complications, including the development of nutritional deficiencies.

Determining which operation is most appropriate for a specific patient depends on several factors, most importantly which diseases need treatment, in addition to the degree of obesity. An analysis of the risks and benefits of each operation for each patient should be undertaken that incorporates medical comorbidities, weight loss needed to obtain health goals, likelihood of patient compliance, and patient preference.

THE PHYSIOLOGY OF WEIGHT LOSS AFTER BARIATRIC OPERATIONS AND PROCEDURES

Weight Loss Mechanisms

All commonly performed bariatric procedures involve a restrictive component that may or may not impact intestinal nutrient handling. Thus, in addition to caloric restriction, altered gastrointestinal anatomy may affect the entero-neuro-endocrine axis involving signaling from multiple gut hormones and metabolites that influence appetite and satiety through endocrine or neural pathways to a varying degree following different bariatric procedures (see Fig. 27.3).

Caloric Restriction

Caloric restriction creates an energy deficit that leads to mobilization of stored energy and weight reduction. The rate and magnitude of weight reduction are related to the degree of energy deficit produced, with very low-calorie diets (<800 kcal/day) leading to more rapid weight loss than low-calorie diets (800–1500 kcal/day) but being more challenging to sustain, and so resulting in a similar effect on long-term weight management.[77]

Diet-induced weight reduction of greater than 10% body weight can be achieved in 8 to 10 weeks but results in neurohormonal adaptation that increases hunger and may promote weight regain in the long-term.[78] Energy expenditure is reduced to a greater extent than that predicted by weight loss alone, an effect shown to persist for more than a year in individuals who have maintained a reduced body weight[79] and favoring weight regain during long-term weight management.

Short-term implementation of a very low–calorie diet, with or without the assistance of an IGB, may be considered for selected patients before bariatric surgery in order to reduce hepatomegaly and visceral adiposity, which can help to reduce surgical risk. Some studies suggest that even modest reduction of body weight by 5% to 10% in the immediate preoperative period may reduce the risk of operative complications[80] and postoperative death.[81]

Gastrointestinal Anatomy Changes

Eating behaviors differ in patients who have had bariatric surgery compared with those on low- calorie diets. Diet-induced weight loss tends to decrease satiety, increase hunger, and drive cravings for energy-dense foods.[82,83] In contrast, patients describe early satiety and less hunger, and the compensatory consumption of energy-rich foods is not observed following bariatric surgery.[84-87] In part, these behavioral changes are related to adaptive learning to avoid adverse gastrointestinal symptoms after surgery, such as nausea, vomiting, diarrhea, reflux, bloating, and dumping syndrome. The character of these symptoms will vary due to differences in the surgical procedures and postsurgical adaptation.

Gastrointestinal and Adipocyte Hormonal Changes

Ghrelin, a peptide hormone mainly produced by X/A cells in the oxyntic glands of the fundus or body of the stomach, acts on the G protein–coupled receptor known as the *growth hormone secretagogue receptor*[9] to stimulate neuropeptide Y–agouti-related protein neurons within the arcuate nucleus (ARC), thereby stimulating hunger and increasing food intake.[88] Most studies show reduced circulating ghrelin following RYGB[89,90] and SG,[91] but increased concentrations following adjustable gastric banding[84] and low-calorie diet,[90,78] suggesting that gastric exclusion may help to reduce hunger that is otherwise increased during weight reduction.

GLP-1, PYY, and oxyntomodulin are anorexic hormones released after meal ingestion from L-cells predominantly located in the mucosal epithelium of the ileum and colon. These peptides act at the hypothalamic ARC and brainstem to induce satiety and reduce food intake.[92] Postprandial levels of these anorexic hormones increase after RYGB[85,93-95] and SG,[82,96] but not with diet-induced weight loss[78,94] or adjustable gastric banding.[97] Similarly, cholecystokinin (CCK), another anorexic peptide released in response to food intake from I-cells located in the mucosal epithelium of the duodenum and jejunum[98] or released in response to GLP-1 or duodenal long-chain free fatty acids,[99] also increases following RYGB and SG.[100,101] In addition, FGF19, which is produced in the ileum in response to bile acid absorption, is increased following RYGB but not with adjustable gastric banding, and has been shown to be an anorexigenic hormone in rodents.[102] Thus, altered intestinal delivery and handling of nutrients and bile acids may act through gastrointestinal hormone changes to promote satiety and contribute to reduction in food intake.

The adipokine adiponectin functions as an insulin-sensitizing hormone regulating glucose and lipid metabolism,[103] with anti-inflammatory properties and beneficial effects on type 2 diabetes, atherosclerosis, obesity, and nonalcoholic fatty liver disease.[104,105] Adiponectin levels increase following bypass and restrictive surgeries, and the magnitude of increase may be larger following RYGB than band surgery, or compared with weight loss by caloric restriction.[83] Leptin, also secreted by adipocytes, acts primarily on the hypothalamus to increase energy expenditure and reduce food intake. Leptin functions as an indicator of energy stores, and so levels decrease in proportion to weight reduction.[106] It remains unclear to what extent changes in adiponectin, leptin, or other adipokine concentrations or activity contribute to weight loss durability and metabolic improvements beyond that seen with weight loss achieved through dietary intervention alone.

Central Nervous System Control

Regulation of food intake can be influenced by the central nervous system by affecting food-seeking behavior and satiety perception. The hypothalamus, frontal cortex, and caudal brainstem regulate weight homeostasis by detecting internal and external signals to stimulate appetite or satiety accordingly.[107] The hypothalamus contains two groups of neurons within the ARC with opposite effects: the proopiomelanocortin (POMC)-derived peptides, which act via melanocortin receptor 4 to reduce food intake and increase energy expenditure, and the orexigenic peptides neuropeptide Y (NPY) and Agouti-related protein (AgRP), which drive food intake.[87] The expression of these peptides (POMC, NPY, and AgRP) may change following bariatric surgery, as illustrated in studies of rats following vertical SG compared with pair-fed rats undergoing sham surgery.[108] AgRP levels were unchanged in the vertical SG group compared with pair-fed animals that had elevated AgRP. These findings suggest that calorically-restricted rats were hungry compared with those with vertical SG.

Neural systems of reward, cognition, and emotion may also contribute to regulation of eating behavior post–bariatric surgery, as shown in studies in humans demonstrating altered effects of food visual cues on brain activity in hedonistic centers assessed by functional magnetic resonance imaging (fMRI).[109] Post-RYGB patients had lower activation of brain reward systems, particularly to energy-rich foods, and chose healthier food options compared with BMI-matched controls or patients who had undergone adjustable gastric band.[109] Suppression of postprandial increases in the satiety hormones PYY, GLP-1, and FGF19 by octreotide increased brain-hedonic responses to anticipatory food reward as assessed using fMRI in individuals following RYGB, but not after adjustable gastric banding.[110] These findings are consistent with the hypothesis that increased gastrointestinal hormone effects resulting from altered gastrointestinal tract anatomy may contribute to long-term regulation of food intake.

Vagal Signaling

Vagal nerve afferent activity also contributes to food intake.[111] Stimulation of the vagal nerve by increased intraluminal pressures may contribute to reduced food intake and weight loss in patients who receive an adjustable gastric band. Patients with optimally filled bands are less hungry compared with patients with suboptimally filled or empty bands, as seen in a randomized, masked crossover study.[84] However, vagal nerve preservation does not influence clinical parameters (weight loss and gastrointestinal symptoms) and satiety scores compared with severing of the vagal nerve during RYGB procedures.[112] Similarly, in animal studies, no significant difference in body weight, body composition, meal patterns, and energy expenditure were found between rats undergoing RYGB alone and RYGB with common hepatic branch vagotomy.[113] Thus, further studies are required to explore the role of the vagus nerve in weight loss induced by bariatric surgical procedures.

Energy Expenditure

Exercise capacity can improve following bariatric surgery.[114] Additionally, human and animal studies demonstrate a lesser reduction in resting energy expenditure following RYGB compared with those with diet-induced weight loss.[115-117] Mechanisms underlying this phenomenon remain incompletely understood but could include increased fitness from increased physical activity after weight loss or mechanisms such as bile acid activation of brown adipose tissue or skeletal muscle oxidation.[118]

KEY POINTS

- Weight loss that follows bariatric procedures is dependent on caloric restriction. In addition, altered gastrointestinal anatomy may affect the entero-neuro-endocrine axis involving signaling from multiple gut hormones and metabolites that influence appetite and satiety.
- Gastric exclusion and altered intestinal delivery and handling of nutrients and bile acids may act through these gastrointestinal hormone changes to promote satiety and reduce hunger, which is otherwise increased during weight reduction.
- Neural systems of reward, cognition, and emotion may also contribute to regulation of eating behavior following bariatric procedures.

PHYSIOLOGIC EFFECTS OF BARIATRIC SURGERY ON CARDIOMETABOLIC HEALTH AND MORTALITY

Diabetes Remission Following Bariatric Surgery

Improvements are seen in glycemia, hypertension, and dyslipidemia in patients with type 2 diabetes following bariatric surgery. A metaanalysis of primarily observational cohort studies by Buchwald and colleagues reported that 78% of patients with type 2 diabetes undergoing bariatric surgery had complete remission of type 2 diabetes, defined as normoglycemia without medication, and 86% had either improvement or resolution of diabetes.[119] Patients who underwent biliopancreatic diversion had the highest remission rate, at 95%, followed by RYGB at 80%, and adjustable gastric banding at 57%. A review of randomized clinical trials by Arterburn and colleagues reported remission of type 2 diabetes in 22% to 90% of patients after RYGB, 19% to 73% after adjustable gastric banding, and 0% to 23% with diet intervention alone.[120] The wide variation in clinical response is thought to be due to a large variance of severity and duration of type 2 diabetes among the studies. Surgical approaches may also reduce the incidence of new diabetes.[121]

When considering patients with type 2 diabetes, greater weight loss and better glycemic outcomes are seen in the early years following bariatric surgery in randomized studies that compare surgical with medical diabetes and weight-management approaches.[122-125] In a randomized clinical trial comparing biliopancreatic diversion, RYGB, and medical therapy, diabetes remission rates of 95% following biliopancreatic diversion and 75% following RYGB compared to 0% with medical therapy at 2 years[124] were sustained at 68% and 42% compared with 0%, respectively, after 5 years of follow-up.[126] In a randomized clinical trial comparing RYGB, SG, and medical therapy, diabetes remission rates of 46% following RYGB and 29% following SG compared with 0% with medical therapy at 3 years[127] were sustained at 31% and 23% compared with 0%, respectively, after 5 years of follow-up.[128] In a randomized clinical trial comparing RYGB and medical therapy, diabetes remission rates of 42% following RYGB and compared with 0% with medical therapy at 2 years[129] were sustained at 16% compared with 0%, respectively, after 5 years of follow-up.[130] In a randomized clinical trial comparing RYGB, adjustable gastric banding, and medical therapy, diabetes remission rates at 5 years were 30% following RYGB and 19% following adjustable gastric banding with to 0% with medical therapy.[131] These studies demonstrate both durable glycemic improvement following bariatric surgical intervention when compared with intensive lifestyle modification in type 2 diabetes, but also the recurrence of diabetes in some individuals over time postoperatively.

While more durable weight reduction with surgical compared with medical intervention likely explains the high numbers of patients who may achieve diabetes remission following bariatric surgery, unsurprisingly, remission from diabetes may not be permanent.[132] Approximately 35% of patients who initially experience remission may relapse within 5 years, with a median duration of remission of approximately 8.3 years. Reoccurrence of diabetes is often associated with weight regain and dietary noncompliance. However, several factors predict lower initial remission and/or subsequent relapse, including poor preoperative glycemic control, longer duration since diagnosis of diabetes, insulin use,[132] and lower β cell glucose sensitivity,[133] together suggesting that adequate residual β cell function is important for initial remission, and that progressive disease may contribute to relapse. However, as many studies demonstrate important clinical benefits from a period of glycemic control on subsequent development of complications (metabolic memory),[134] even moderate-duration remission may be clinically important. Emerging evidence suggests that RYGB may lead to more durable weight reduction and improvement in glycemic control than SG.[120]

Caloric restriction and weight loss each have a substantial impact on improvement and remission of diabetes, but there is great interest in the hypothesis that additional mechanisms contribute to improvement in glucose homeostasis, and this remains heavily debated. While glycemic improvements occur within days following RYGB,[135,136] this effect may be explained by the perioperative caloric restriction,[137] as observed with other gastrointestinal surgery. Weight loss achieved by RYGB and SG is greater than that achieved by diet and exercise or conventional medical therapy, which most likely explains the greater improvement in glucose tolerance with surgical compared with medical intervention.[124] Neither liposuction nor surgical resection of omental fat corrects diabetes,[138,139] such that fat loss alone is insufficient for metabolic improvement.

The Role of Insulin Sensitivity and Insulin Secretion in Diabetes Remission after Gastric Bypass

Persons with type 2 diabetes are typically more insulin-resistant than persons without diabetes. There are parallel improvements in insulin sensitivity following RYGB in persons with or without type 2 diabetes, although those with diabetes continue to have lower insulin sensitivity at any given BMI.[133] Improvements in glucose utilization are greater early after RYGB in persons with type 2 diabetes compared with those without diabetes, presumably due to elimination of glucotoxic effects. However, by 1 year glucose utilization is similarly improved for those who did or did not have diabetes at the time of surgery. Early postoperative improvements in glycemia are mediated in part by improved insulin suppression of endogenous (primarily hepatic) glucose production, accompanied by decreased oxidative glucose disposal and increased lipid oxidation.[140] Effects of biliopancreatic diversion on insulin sensitivity appear greater in proportion to weight lost.[141] Following RYGB, hepatic insulin sensitivity is increased significantly in individuals with type 2 diabetes compared with nonsurgical controls with type 2 diabetes assessed at matched 10% weight loss; however, time to 10% weight reduction occurred more quickly with surgical versus nonsurgical intensive lifestyle intervention,[142] indicating that greater caloric restriction may explain the difference in hepatic glucose metabolism.[143,144] In contrast, improvement in insulin sensitivity following adjustable gastric banding appears proportionate to weight lost.[93] Similar improvements in insulin sensitivity have been reported in individuals who achieve 20% weight reduction, whether by RYGB, SG, or gastric banding.[145,146]

There is a robust early increase in insulin secretion, GLP-1, and β cell glucose sensitivity following a mixed meal after RYGB, but not adjustable gastric banding, at similar weight loss.[147] This is best explained by altered nutrient transit with accelerated delivery to the distal small intestine, leading to more rapid glucose absorption and exaggerated GLP-1 and insulin responses.[145,148] Although improved from baseline, β cell glucose sensitivity after RYGB remains lower in patients with type 2 diabetes compared with those without.[133] Importantly, despite an exaggerated postsurgical GLP-1 response to nutrient ingestion, postprandial glucose tolerance improved similarly in individuals with type 2 diabetes after RYGB or intensive lifestyle modification when assessed at a similar 10% weight reduction.[142] Furthermore, blockage of the GLP-1 receptor during meal ingestion resulted in similar deterioration of postprandial glucose tolerance in those treated by surgery or diet, providing evidence against a greater contribution of GLP-1 to postprandial glucose metabolism following surgical weight loss.[142]

The Hindgut and the Foregut Hypotheses

Two general leading hypotheses have been proposed to explain the effects of bariatric surgery on improved glycemia: the hindgut hypothesis and the foregut hypothesis. The hindgut hypothesis proposes that glycemic improvement is due to accelerated nutrient delivery to the distal intestine, which augments secretion of hormones that affect satiety and glucose homeostasis, including GLP-1, PYY, oxyntomodulin, and/or CCK.[101] However, increased delivery of nutrients to the proximal small intestine as occurs with RYGB and SG may stimulate distal enteroendocrine cell secretion via activation of an entero-enteric neural reflex. The foregut hypothesis suggests that exclusion of the proximal intestine from ingested food promotes antidiabetic effects by inhibiting an unidentified signal that promotes insulin resistance,[149] but it is more likely that altered nutrient digestion and accelerated distal delivery are responsible for these effects.

Branched-Chain Amino Acids and Aromatic Amino Acids

The branched-chain amino acids (BCAAs) valine, leucine, and isoleucine are among the nine essential amino acids (AAs) available to humans as dietary proteins. BCAAs and the aromatic AAs, especially phenylalanine and tyrosine, are associated with obesity and insulin resistance,[150-152] and BCAA concentrations decrease with weight loss.[150] Greater reductions in circulating BCAAs and AAs are seen in type 2 diabetes following gastric bypass compared with patients with nonsurgical, matched weight loss.[153] Reductions in BCAA correlate with improved insulin sensitivity estimated by homeostatic model assessment of insulin resistance or euglycemic clamp.[152,154] However, other studies showed BCAA decrease similarly after RYGB compared with matched weight loss following adjustable gastric banding in nondiabetic individuals,[152] so further studies are required to determine the causal significance of the relationship between AAs and modification of insulin sensitivity, and whether the magnitude of effects differ following surgically-induced weight loss.

Bile Acids

Bile acids are well recognized for their role in lipid metabolism. Recently they have been found to have additional metabolic effects affecting gut peptide secretion, energy expenditure, and glucose homeostasis.[155] RYGB leads to changes in the delivery of bile acid and nutrient flow through the gut. Diverting bile from the common bile duct to drain into distal jejunum with a catheter increases serum bile acids and postprandial GLP-1 response and improves glucose tolerance and hepatic steatosis compared with sham-operated rats.[156] Bile acids promote GLP-1 secretion through the G protein–coupled receptor TGR5.[157] Intrarectal infusion of the bile salt taurocholic acid increases plasma GLP-1, PYY, and insulin concentrations in obese men with type 2 diabetes,[158] and oral tauroursodeoxycholic acid improves liver and muscle insulin sensitivity in obese men.[159] Circulating bile acid concentrations increase following RYGB.[160,161] Increased circulating bile acids are associated with increased GLP-1 and improved glycemia,[160,162] but not with skeletal muscle insulin sensitivity, insulin response to mixed meal, or resting energy expenditure.[162] Changes in circulating bile acids are less pronounced after adjustable gastric banding compared with RYGB.[162] The relative importance of altered bile acids in improved metabolism also remains incompletely understood.

Gut Microbiota

The gut microbiota profile differs in individuals with obesity and metabolic syndrome compared with lean individuals. Recently, gut microbiota have been recognized to alter production or bioavailability of small molecules, proteins, and nutrients, and to contribute to inflammation in the host.[163,164] Changes in the dynamic symbiotic relationship between the microbiota and the host participate in the progression of obesity and diabetes. However, with a diversity of microorganisms present and a variety of factors that can affect the microbiome composition (such as dietary macronutrients, anatomic variance, antibiotic usage, pH, and bile flow), identifying the specific relationship between various gut microbiota and obesity remains a challenging field of investigation. RYGB causes shifts in the gut microbiome, including a change in ratio of Firmicutes to Bacteroidetes phyla and an increase in colonization with *Proteobacteria*.[165] Transfer of gut bacteria from mice that have undergone RYGB to unoperated germ-free mice promotes weight loss and reduced fat mass in recipient mice, suggesting that changes in gut microbiota contribute to weight loss following RYGB.[166] Changes in gut microbiota may be relevant to humans. Intriguingly, Vrieze and coworkers[167] infused microbiota from lean human donors into the duodenum of obese individuals and showed improved insulin sensitivity, independent of weight change.

Cardiovascular Disease and Mortality

The hallmark prospective Swedish Obese Subjects (SOS) study compared adjustable or nonadjustable gastric banding, the restrictive but now outdated vertical banded gastroplasty, and RYGB to medical management in well-matched but nonrandomized obese cohorts. After bariatric procedures, the combined surgical cohort lost an average of 16.1% of total body weight at 10 years compared with a slight weight gain in the nonsurgical management group.114 RYGB resulted in greater mean weight loss (–25%) than vertical banded gastroplasty (–16.5%) and adjustable gastric banding (–13.2%) at 2 years and 10 years. Overall, the surgical group had more favorable outcomes, with both improved resolution and lower incidence rates of type 2 diabetes, as well as reduced hypertriglyceridemia and hyperuricemia compared with medical management. Hypertension and dyslipidemia likewise improved,[168,169] which together would be anticipated to reduce major cardiovascular event rates and improve survival. Indeed, both the SOS study and a retrospective cohort study demonstrated improved total mortality by 30% to 40% in surgically treated groups.[170,171] Neither study was randomized; thus, referral biases could confound conclusions. Death attributed to cardiovascular disease was reduced by approximately 50%,[170,172] and deaths from diabetes listed on the death certificate were reduced by 90%.[45,170] Incident diabetes was reduced by approximately 80%.[48,121] Indeed, multiple obesity-related comorbidities have been shown to improve following bariatric surgery, including a reduction in cancers and an improvement in metabolic, cardiovascular, reproductive, musculoskeletal, respiratory, and some psychiatric conditions (Table 27.1).[168,171,173-176] With now over 20 years' follow-up in the SOS study, bariatric surgery has remained associated with a lower risk of death from both cardiovascular disease and cancer; however, survival following bariatric surgery remained lower than in the general population.[177]

Other studies that have examined the effect of bariatric surgery on hypertension and dyslipidemia include the GATEWAY study, a randomized trial of the effects of bariatric surgery in obese patients with hypertension, which determined that bariatric surgery represents an effective strategy for blood pressure control in a broad population of patients with obesity and hypertension.[178] A comparative systematic review and metaanalysis determined that obese patients treated with RYGB present a higher hypertension remission rate at 1 and 5 years compared with SG.[179] Other studies have noted that RYGB and SG obtain similar rates of remission of hypertension, but RYGB reaches significantly greater rates of dyslipidemia remission.[180]

KEY POINTS

- Patients with type 2 diabetes experience durable improvements in glycemia, hypertension, and dyslipidemia following bariatric surgery compared with intensive lifestyle modification, although recurrence of hyperglycemia occurs in some individuals over time postoperatively.
- Adequate residual β cell function is important for initial remission of type 2 diabetes, and progressive disease may contribute to relapse. Insulin sensitivity is improved by and proportionate to both caloric restriction and weight loss.
- Multiple additional obesity-related comorbidities have been shown to improve following bariatric surgery, including a reduction in cancers and an improvement in metabolic, cardiovascular, reproductive, musculoskeletal, respiratory, and some psychiatric conditions (Table 27.1).

TABLE 27.1 Improvements in Obesity Comorbid Conditions

Mortality

Multiple cohort matched studies suggest improved mortality.

Cardiometabolic

- Major cardiovascular event rates (myocardial infarction, stroke, and cardiovascular death)
- Type 2 diabetes

Nephropathy related to diabetes

- Type 2 diabetes prevention
- Hypertension
- Dyslipidemia
- Hyperuricemia

Respiratory

- Obstructive sleep apnea
- Obesity hypoventilation

Gastrointestinal

- Nonalcoholic fatty liver disease and nonalcoholic steatohepatitis

Musculoskeletal

- Degenerative joint disease (osteoarthritis of weight-bearing joints)
- General physical functioning and exercise capacity
- Recovery and rehabilitation following joint surgery

Dermatological

- Hirsutism
- Intertrigo and candidiasis
- Wound healing
- Striae/stretch marks
- Acanthosis nigricans

Reproductive System

- Polycystic ovarian disease
- Improved fertility (female and male)
- Regulation of menstrual cycle
- Libido

Oncology

- Reduction in overall cancer risk and mortality

Psychosocial/Neurologic

- Quality-of-life health measures
- Cognitive function (improvement in learning and memory)
- Pseudotumor cerebri (intracranial hypertension)

Urology

- Urinary incontinence

IMPACT OF BARIATRIC SURGERY ON OTHER OBESITY-RELATED COMORBID CONDITIONS (TABLE 27.1)

Polycystic Ovarian Syndrome and Fertility

Obesity negatively impacts fertility in women.[181,182] In the United States, women in their reproductive years account for 83% of those undergoing bariatric surgery.[168,183]

Multiple studies have demonstrated improvements in polycystic ovarian syndrome (PCOS) and the associated clinical sequelae of menstrual irregularity, hirsutism, and infertility after bariatric surgery. One study showed that the incidence of PCOS decreased by nearly 40% at study endpoint, with nearly 50% improvement in menstrual irregularity and 30% improvement in hirsutism.[184] Other studies have confirmed these findings.[185,186] In one, pre- and postoperative anthropometric evaluations, menstrual cyclicity, and ovarian volume (OV), as well as markers of hyperandrogenism, dyslipidemia, and dysglycemia were evaluated and compared to a non-PCOS control group. The PCOS patients had a significant reduction in androgen levels and fewer met the criteria for hyperandrogenism and irregular menses. OV did not significantly decline in either group postoperatively.[187] A retrospective study examining 796 female patients after biliopancreatic diversion found that 47% of women previously unable to conceive preoperatively were successful postoperatively and 82% of these women had appropriate weight gain during pregnancy.[188] Miscarriage rates were not improved (26%).

Pulmonary Disease, Including Obstructive Sleep Apnea

Obesity has significant effects on respiratory function, contributes substantially to the burden of respiratory disease, and is linked with many respiratory symptoms and diseases, including exertional dyspnea, obstructive sleep apnea syndrome, obesity hypoventilation syndrome, chronic obstructive pulmonary disease (COPD), asthma, pulmonary embolism, and aspiration pneumonia. Not surprisingly, the weight loss associated with bariatric surgery has a favorable effect on pulmonary disease. Resolution of obstructive sleep apnea after bariatric surgery occurs in 66% of patients.[189,190] In one study, emergency department visits and hospitalizations for acute exacerbations of COPD decreased in obese patients after bariatric surgery.[191]

Gastroesophageal Reflux Disease

Because obesity is a risk factor for GERD, its prevalence in this population is elevated. GERD has become an important comorbidity to consider, because the two most common operations for obesity have diametrically opposed effects on GERD. *De novo* GERD develops in up to 50% of patients after SG, while those with preexisting GERD symptoms can expect a worsening of their symptoms after SG.[192] Consequently, most consider preexisting moderate or severe GERD and Barrett's esophagus to be a contraindication to SG. On the other hand, the RYGB is an excellent operation for the treatment of GERD. The anatomy of a RYGB diverts both acid (produced from parietal cells generally located in the bypassed stomach) and bile away from the distal esophagus. Seventy-eight to one hundred percent of patients with preexisting GERD experience either improvement or remission of GERD at 12 to 18 months postoperatively.[193,194]

Pseudotumor Cerebri

Idiopathic intracranial hypertension is a rare condition that typically affects young women with obesity. Elevated cerebral spinal fluid pressures in the brain can result in symptoms of headache and visual field loss and blindness due its detrimental effects on neural structures, such as excessive pressure on the ophthalmic nerve.[195] Surgical weight loss can correct this condition; a recent systematic review and comparison of metaanalyses suggested that weight loss surgery was superior to nonsurgical weight loss for the treatment of idiopathic intracranial hypertension.[196]

Cancer

There is a strong association between obesity and many difference types of cancers.[197,198] Although the exact mechanisms have not been established, increasing evidence demonstrates that bariatric surgery decreases this risk. In one multisite cohort of patients with severe obesity, bariatric surgery was associated with a lower risk of incident cancer, particularly obesity-associated cancers, such as postmenopausal breast cancer, endometrial cancer, and colon cancer.[199]

COMPLICATIONS OF BARIATRIC OPERATIONS AND PROCEDURES (TABLE 27.2)

Overall, operations for obesity are remarkably safe, particularly given the pervasive disease of obesity, which affects multiple organ systems and creates a challenging operative environment in terms of inflamed tissues and difficult intraabdominal exposure. Despite these issues, the risk of perioperative death is no more than that for a cholecystectomy, hip replacement, and hysterectomy, approximately 0.2%.

TABLE 27.2 Potential Complications of Bariatric Surgery

Early Complications (Within 30 Days of Surgery)

Hemorrhage
Infections
Anesthetic complications
Wound complications
Deep venous thromboembolism
Pulmonary embolism
Cardiorespiratory events
Technical failure
Anastomotic or staple line leaks (excludes adjustable gastric banding)
Perioperative mortality

Late Complications

Gastric esophageal reflux
Anastomotic ulcers
Fistulas and strictures
Reoperation

Life-Threatening Complications

Internal hernia
Bowel obstruction
Intussusception

Long-Term Metabolic Complications

Malnutrition
  Roux-en-Y gastric bypass—Iron, vitamin B_{12}, calcium, vitamin D, secondary hyperparathyroidism, folate
  Biliopancreatic diversion—Protein calorie malnutrition and fat-soluble vitamin deficiency
Nausea and vomiting (may lead to thiamine deficiency)
Inadequate weight loss/weight regain
Dumping syndrome
Hypoglycemia
Hernia
Gallstone formation (secondary to rapid weight loss)
Small intestinal bacterial overgrowth

Complications Specific to Gastric Band

Esophageal dilation and dysmotility
Gastric outlet obstruction
Band slippage
Band erosion
Subcutaneous port complications—pain, leak

Early Complications

Early surgical complications are defined as complications occurring within 30 days of operation. Fortunately, the most serious complications are the least common. These include gastrojejunal anastomosis leakage (<1%), pulmonary embolus (0.5%), bleeding (2%), bowel obstruction (2%), internal hernia (when small bowel anastomoses are performed) (2%), cardiorespiratory events, and wound complications. The incidence of wound complications such as infection and abdominal wall hernia is generally high in the obese but has decreased by 10-fold or more with the use of laparoscopy. One long-term multicenter consortium assessed a composite endpoint of death, thrombotic event, reintervention, or prolonged hospital stay (more than 30 days) and noted an incidence of 4.1% after bariatric surgery.[200]

LATE AND CHRONIC COMPLICATIONS

Complications occurring after 30 days postoperatively that are strictly related to surgery include gastrojejunostomy anastomotic stricture and marginal ulceration (5%–10%), small bowel obstruction (2%), and internal hernia (2%). As discussed above, GERD can develop in up to 50% of patients after vertical SG.[192] Long-term complications that can present a diagnostic and management challenge to the surgeon and nonsurgeon alike are discussed in detail below.

WEIGHT REGAIN

The most common late complication is failure to lose adequate weight or weight regain, which can occur in up to 20% of patients. Most often this is the result of lack of compliance with postoperative diet and exercise recommendations and patient attrition to follow-up, particularly with their bariatric program.[201] The initial rate of postoperative weight loss can be somewhat variable and is not generally an accurate predictor of ultimate weight loss outcome. Although this variability can be, in part, related to the operation itself, it may be more dependent on beginning weight/BMI and other patient factors, including behavioral compliance with respect to diet and exercise. However, the majority of weight loss typically occurs in the first 18 to 24 months.

Successful weight loss after bariatric surgery is generally defined as at least 50% EWL or a TBWL of at least 20%.[202] Patients with BMI above 50 kg/m^2 are at greater risk for weight regain.[203,204] Potential causes for weight regain can be patient-related, anatomy-related, or both. Patient-related etiologies may include poor dietary compliance, physical inactivity, inadequate follow-up, and/or mental health disorders.[205-208] Sometimes a new medication is the cause; it is well-established that antidepressants (particularly selective serotonin reuptake inhibitors and tricyclic antidepressants), mood stabilizers (particularly atypical anti-psychotic agents), and certain anti-hyperglycemic agents (particularly insulin, sulfonylureas, and thiazolidinediones) diabetic medications can all cause weight gain. Adjuvant use of weight loss medications can arrest weight regain and augment weight loss in patients after bariatric surgery.[209,210]

Anatomic causes of weight regain are sometimes present and need to be evaluated. After RYGB these can include dilation of the gastrojejunal stoma, which causes decreased satiety. Although very unlikely in the case of the contemporary RYGB due to modification of technique, a RYGB performed in the distant past may have a dilated gastric pouch or gastrogastric fistula as a cause for weight regain. Anatomic abnormalities that can cause weight regain after SG include dilated gastric sleeve and retained fundus. Many of these anatomic conditions can be endoscopically and surgically corrected.[210,211]

DUMPING SYNDROME

Dumping is a result of the anatomical configuration specifically associated with the RYGB and is a consequence of neurohormonal changes that occur, with rapid emptying of carbohydrates into the jejunal Roux limb. Whether this should be considered a true complication is debatable, because it is not dangerous, and those who develop episodes of dumping are typically straying from the prescribed postoperative diet for achieving the desired outcome of weight loss. Dumping has both early and late components. Early dumping is characterized by symptoms of bloating, abdominal discomfort, diarrhea, tachycardia, and lightheadedness and results from the delivery of hyperosmolar food into the small intestine causing a shift of fluid intraluminally from the intravascular compartment. Late dumping occurs within 2 to 3 hours of eating and is characterized by symptoms of diaphoresis, dizziness, and weakness that result from the rapid small intestine absorption of the ingested high glucose load, resulting in early hyperglycemia and consequent hyperinsulinism leading to late post-prandial or "reactive" hypoglycemia. Dumping after RYGB is considered an anticipated check on eating behavior and maintenance of dietary compliance. The threat of this unwanted side effect can be useful to encourage patients to avoid liquid carbohydrates or other foods with high sugar content. Those who experience episodes of dumping should undergo further dietary counseling. Generally, dumping can be avoided completely with dietary modification. However, there is growing evidence that at least some forms of dumping can be treated by endoscopic narrowing of the gastrojejunostomy stoma to reduce the rate of emptying of the gastric pouch, with improvement of symptoms.[212,213]

Alimentary Hypoglycemia with Neuroglycopenia

Alimentary hypoglycemia, also called post–gastric bypass hypoglycemia, is a rare condition that has some similarities with late dumping syndrome in terms of both symptoms and mechanism. Its prevalence is largely unknown, but it appears to be well below 1%,[214,215] although some studies have suggested a much higher incidence.[216,217] It can potentially occur with any upper gastrointestinal tract surgery that accelerates nutrient delivery to the small intestine, especially gastrectomy and RYGB with anatomical shortening of the upper gastrointestinal tract.[218,219] It has been described after operations that accelerate gastric emptying, such as fundoplication and SG, but is much less common after these operations.[220]

The general mechanism is thought to involve the release, in response to a high carbohydrate meal, of a high concentration of insulin due to the previous low insulin sensitivity of the obese state prior to surgery. However, after substantial weight loss this degree of insulin production is inappropriate, and hypoglycemia, sometimes severe with neuroglycopenia, can result. Peak insulin levels can be as high as 500 μU/l.[214] Mixed meal testing has demonstrated that, after a high-carbohydrate mixed meal, hyperglycemia associated with hyperinsulinemia is noted around 30 minutes. Hypoglycemia then develops as the serum insulin rapidly declines. A nadir is reached at approximately 120 minutes, and the plasma glucose level spontaneously corrects. After a low-carbohydrate high-protein mixed meal there is very little change in plasma glucose and only a modest increase in serum insulin.[214] Rapid nutrient delivery and absorption result in exaggerated early postprandial levels of glucose, GLP-1, and consequently insulin, with hypoglycemia typically occurring 1.5 to 3 hours after meals. Rarely, patients develop severe hypoglycemia with neuroglycopenia, manifested by confusion, loss of consciousness, seizures, and/or motor vehicle accidents.[221,222] When compared with postsurgical controls without hypoglycemia, individuals with alimentary hypoglycemia exhibit dysregulated islet function with increased insulin secretion and reduced insulin clearance, likely contributing to the development of late postprandial hypoglycemia.[223] The enhanced β cell sensitivity to glucose may be dependent, at least in part, on the exaggerated GLP-1 response, because blockage of the GLP-1 receptor prevents postprandial hypoglycemia in affected individuals that is associated with greater reduction in postprandial insulin secretion than that observed in postsurgical controls without alimentary hypoglycemia.[224] Counterregulatory responses to defend against the development of hypoglycemia are also impaired following RYGB, including marked reductions in glucagon and epinephrine secretion in response to insulin-induced hypoglycemia.[225] Because exposure to even mild hypoglycemia, as may occur frequently after meals, can blunt counterregulatory responses to hypoglycemia, it is possible that induction of hypoglycemia-associated autonomic failure may also contribute to the development of neuroglycopenic hypoglycemia long-term following bariatric surgery.

Initial management involves dietary modification, emphasizing controlled portions of low–glycemic index complex carbohydrates ingested together with protein and fat in order to slow the rate of glucose absorption into the circulation, as well as attention to correcting macro- and micronutrient deficiencies. Treatment of individual hypoglycemic episodes should include protein in addition to carbohydrate in order to prevent cyclic hypoglycemia. Patients should be advised to ingest low-carbohydrate, protein-rich foods, with sources of carbohydrate complex rather than simple. To prevent hypoglycemic episodes, alpha-glucosidase inhibition (i.e., acarbose) to slow carbohydrate absorption and minimize postprandial glycemia and thus reduce the stimulus for insulin secretion or use of somatostatin analogs or diazoxide to suppress insulin secretion may be effective.[226] Somatostatin has been used with varying degrees of success. Glucagon has recently emerged as potential therapy for treatment of postprandial hypoglycemia.[227] New liquid formulations may soon enable automated rescue dosing of pump-delivered glucagon informed by continuous glucose monitoring, which has been shown to reduce severe hypoglycemia in individuals.[228,229] Altering the route of nutrient delivery through gastrotomy tube placement[230] for short-term management and deconstruction of RYGB for long-term treatment have been tried, with general success. Outcomes after partial pancreatectomy are variable and appear to be no more effective than dietary modification. Moreover, pancreatectomy has high morbidity and thus is no longer considered an acceptable form of treatment.[221] As discussed above, reducing the rate of gastric emptying by decreasing the size of the gastrojejunostomy stoma via endoscopic transoral outlet reduction has been shown to be effective for treating dumping symptoms and is a promising strategy for alimentary limb hypoglycemia when the stoma is greater than 2 cm in diameter.[212,213]

KEY POINTS

- Alimentary hypoglycemia can occur after upper gastrointestinal tract rearrangement but is most commonly seen after Roux-en-Y gastric bypass. Synonyms include hyperinsulinemic hypoglycemia, and post–gastric bypass hypoglycemia.
- Symptoms can be similar to late dumping and include diaphoresis, tachycardia, mental fogginess, confusion, and, if severe, loss of consciousness and seizure. The most severe symptoms occur when there is associated neuroglycopenia.
- The mechanisms appear to involve exaggerated early postprandial levels of glucose, glucagon-like peptide 1, and consequently insulin, with hypoglycemia typically occurring 1.5–3 hours after rapid delivery and absorption of a high carbohydrate meal.
- The first line of treatment involves diet modification to a high-protein, low-carbohydrate diet. Medications such as acarbose, diazoxide, and somatostatin can be added as needed. Recently, glucagon is being considered as a potential therapy. Surgical options include reversal of anatomic changes (e.g., gastric bypass reversal) and endoscopic narrowing of the gastrojejunal stoma. Pancreatectomy is no longer considered a valid treatment.

Nutrient Deficiencies. Nutrient and vitamin deficiencies can occur following surgical manipulation of the gastrointestinal tract. After bariatric surgery, such deficiencies are seen in operations with a malabsorptive component such as BPD-DS and RYGB. Nutritional deficiencies can also occur to a lesser extent after restrictive operations due to poor food choices, decreased overall intake, or rarely from hyperemesis. Persistent hyperemesis with prolonged poor oral intake should prompt suspicion for low vitamin B1 (thiamine) levels, and supplementation should be given immediately. Gastrectomy can lead to iron, zinc, and vitamin B-12 deficiencies.[231] Preoperative screening and education, typically by a registered dietician, is vital in the assessment of candidates. All patients should be introduced to the Recommended Dietary Allowances as prescribed by the United States Department of Agriculture, should be made aware of the metabolic effects of their operation and its effects on their physiology, and should be educated that they will require lifelong vitamin and mineral supplementation to avoid deficiencies. A daily multivitamin and vitamin B12 supplementation for all bariatric patients, regardless of operation, is safe practice. Supplementation with iron, copper, and calcium is recommended after RYGB. Those with true malabsorptive anatomy (e.g., BPD-DS) may also require routine fat-soluble vitamin supplementation. Although uncommon, deficiencies can occasionally develop despite patient compliance, due to poor diet or extreme malabsorption.

Protein Deficiency. Protein status is often assessed by serum albumin, with a level of less than 3.5 g/dL indicating deficiency. Overall incidence has been estimated to range from 5% to 9% after RYGB and 10% to 15% after BPD-DS at 2 years' postoperative follow-up[232] and can present with muscle weakness/asthenia, alopecia, edema, anemia, or hypoalbuminemia of varying degrees. Management depends upon the severity of the deficiency and the available routes for replenishing protein levels. Over-the-counter low-carbohydrate, high-protein shakes can be useful in those who can tolerate oral intake. When the *per os* route is not available, enteral feeding via a percutaneously, endoscopically, or surgically placed feeding tube may be needed and is preferred over the parenteral route. After gastric bypass enteral feeding is typically accomplished via a remnant gastrostomy tube. Dietary counseling to encourage increased patient intake can correct less profound deficiencies when the oral route is available.

Iron Deficiency. Iron deficiency can be present in the obese population both before and after bariatric surgery. In a systematic review, Enani et al. reported an incidence of iron deficiency of 15.2% before bariatric surgery and 16.6% after bariatric surgery (36.6% before SG vs. 12.4% after SG and 12.9% before RYGB vs. 24.5% after RYGB).[213] The occurrence of iron deficiency anemia was 1.6% after SG and 16.7% after RYGB.[213] Risk factors for postoperative iron deficiency were preoperative iron deficiency, duration of follow-up, and premenopausal status. However, in a bariatric patient presenting with anemia, other common causes must be ruled out before attributing this deficiency solely to the bariatric operation (e.g., menorrhagia, marginal ulcers, or cancer). Ferrous rather than ferric preparations are favored because of relative achlorhydria after RYGB. Supplementation with oral ferrous sulfate, ferrous fumarate, or ferrous gluconate to provide up to 150 to 200 mg of elemental iron daily is recommended, and scheduled follow-ups and labs are important for prevention and management.

Vitamin Deficiency. *Vitamin B-12.* Vitamin B-12 is absorbed in the distal ileum. Intrinsic factor (IF), a glycoprotein made in the parietal cells of the stomach fundus, is required for absorption in the ileum, and gastric acidity greatly facilitates the binding of IF to vitamin B-12 in the stomach. In SG and BPD-DS, gastric IF and acid production is reduced; in RYGB, it is bypassed and defunctionalized.[233] Brolin et al. reported the incidence of vitamin B-12 deficiency at 8% to 37%.[234] Vitamin B-12 deficiency can lead to megaloblastic anemia. However, in folate-supplemented patients, neurological manifestations of vitamin B-12 deficiency without anemia predominate. Compliance with postoperative bariatric supplementation is sufficient to prevent and treat vitamin B-12 deficiency.

Vitamin B9/folate. Folic acid/folate are absorbed in the jejunum. Incidence of deficiency mirrors that of vitamin B-12. However, symptomatic folate deficiency is rare and can result in neural tube defects in a mother's fetus, macrocytic anemia, peripheral neuropathy, cognitive deficiencies, mouth ulcers, and sore/swollen tongue. Multivitamins usually contain the recommended dose of folate.

Vitamin B1/thiamine. Like folate, thiamine is a water-soluble vitamin absorbed in the jejunum. Incidence of thiamine deficiency is low and is seen in patients who are noncompliant with supplementation, those suffering from frequent vomiting, and those with significant malnutrition. The diagnosis of thiamine deficiency is based on fasting blood thiamine (deficiency defined as less than 78 nM). Thiamine deficiency can lead to Wernicke–Korsakoff encephalopathy, and thus a low index of suspicion for diagnosis and treatment is essential. Primavera et al.[235] showed a rate of Wernicke–Korsakoff encephalopathy of 0.18% in 1663 patients. Such patients respond well to intravenous/intramuscular thiamine.

Vitamin D deficiency, calcium deficiency, and bone health. Deficiencies of vitamin D and calcium occur together in bariatric patients. Vitamin D deficiency is the most common deficiency in pre–bariatric surgery obese individuals, and it is important to screen and treat deficient patients preoperatively.[212] Postoperatively, bariatric patients are at risk for metabolic bone disease. After RYGB, early catabolic bone remodeling, as evidenced by increased circulating levels of markers of bone turnover, have been found that persist, and subsequent decrease in bone mineral density can occur.[226,236-238] The mechanism is likely multifactorial. First, bone remodeling after bariatric surgery may represent a physiologic change in skeletal structure in response to skeletal unloading after rapid weight loss. Second, calcium and vitamin D deficiencies with or without secondary hyperparathyroidism can result in pathologic mechanisms that can lead to bone catabolism.[239] Finally, procedures that involve intestinal bypass can lead to deficiencies. Calcium is absorbed in the duodenum and proximal jejunum. Vitamin D, a fat-soluble vitamin, is absorbed in the ileum. A randomized study[128] comparing SG with RYGB versus intensive medical therapy in diabetic obese patients evaluated bone turnover by measuring bone formation marker osteocalcin, bone resorption marker serum C-telopeptide of type 1 collagen, and intact parathyroid hormone at baseline and at 5 years after surgery. Bone turnover was found to be highest for RYGB and was also elevated after SG, but to a lesser extent, and both RYGB and SG were significantly elevated compared with intensive medical management.[240]

Screening should include not only levels of calcium and 25-hydroxyvitamin D, but also parathyroid hormone and markers for bone turnover such as bone-specific alkaline phosphatase, serum C-telopeptide, urinary N-telopeptide and/or osteocalcin.[231] Higher-risk patients, stratified by age and gender, may require a baseline bone density scan and be marked for more stringent postoperative follow-up. Peterson et al. reported a vitamin D deficiency prevalence of 13% to 90% preoperatively.[241] The same study reported a similar prevalence post–bariatric surgery, but it was higher in RYGB patients. In fact, deficiency can occur despite patient compliance.

Vitamins A, E, and K. Deficiencies in these fat-soluble vitamins are mostly seen in patients after a primarily malabsorptive operation, such as the BPD-DS. Reported incidence is low, and clinical presentations are rare and limited to a few case reports typically seen in late follow-up (after 4 years). Vitamin A deficiency, which can cause night blindness and xerophthalmia, has a reported incidence of 5% to 12%. Vitamin E deficiency was reported in 5% in one small study, though no clinically significant complications were reported. Vitamin K deficiency was reported as prevalent post-BPD in one study of 170 patients (68% at 4 years).[231] It has not been shown to be accompanied by any increase in incidence of abnormal bleeding.

Zinc. Zinc deficiency has been reported at rates of 10.8% to as high as 50% in patients following the malabsorptive surgeries BPD and distal RYGB.[231] Blood zinc should be checked in long-term follow-up. Patients with zinc deficiency can present with persistent alopecia.

Selenium. Selenium deficiency occurred at rates of 14.5% in BPD patients in one study, with significant clinical complications.[231] Selenium is needed to convert T4 to the active form T3, and thus hypothyroidism can occur if it is absent.

Magnesium. Magnesium levels should be checked in postoperative patients, because a deficiency can have cardiovascular complications and cause hypocalcemia by impairing parathyroid hormone release. The reported incidence in BPD-DS patients was 5%, with no significant clinical complications.[231]

Copper. Hematologic abnormalities and neuropathies including a form of myelopathy have been described from copper deficiency after RYGB.[242] Although symptomatic deficiency is rare, there is a 10% incidence overall of copper deficiency after RYGB. Copper deficiency myelopathy is a condition indistinguishable from subacute combined degeneration of the spinal cord. Early diagnosis and treatment are crucial to avoid permanent neurologic sequelae. Prophylactic supplementation with at least 2 grams of copper daily is recommended.[243]

Cognitive and Psychological Issues. The National Institutes of Health recognized the importance of a patient's mental health by mandating preoperative psychological evaluation and clearance for all prospective bariatric patients. No patients with active untreated psychosis should be approved for surgery. Drug and alcohol addiction and eating disorders are all contraindications to surgery. Obese patients have a higher incidence of major depressive disorders, anxiety disorders, eating and binging disorders, and emotional eating than nonobese patients. Several health-related quality of life (HRQOL) surveys show that the majority of patients improve in their overall mental and physical health after bariatric surgery. In a study of bariatric patients matched with obese patients who were denied bariatric surgery, RYGB patients scored the highest on a HRQOL survey as far out as 6 years.[244] HRQOL scores correspond directly to weight loss, weight stability, and weight regain. A small subset of patients experience declining mental health postoperatively. Postoperative bariatric patients account for 6% of all inpatient treatment admissions for substance abuse.[245] The etiology for increased substance abuse has been attributed to increased peak blood levels with faster onset and stronger effect, addiction substitution from food to alcohol, new social status and attention received from being thin, and unresolved psychological problems. In fact, one third of patients experienced new-onset alcohol use or abuse after bariatric surgery.[246] In addition, the effect of alcohol consumption after RYGB is pronounced, in that peak alcohol levels occur quickly and disappear rapidly after consumption. This pattern may be a risk factor for alcohol addiction in these patients.[247] Thus, postoperative psychological counseling is indicated, but the cost can be prohibitive. The multidisciplinary team must identify at-risk patients during preoperative assessment.

KEY POINTS

- Nutritional deficiencies can occur after any bariatric operation or endoscopic procedure.
- The most profound nutrient deficiencies are associated with bariatric operations that provide protein-calorie malnutrition as the main mechanism of weight loss.
- Long-term nutritional supplementation and postoperative monitoring are necessary to prevent profound nutritional deficiencies.
- Nutritional deficiencies should be strongly considered in a patient with profound weight loss and adult "failure-to-thrive" even several years after a bariatric operation or endoscopic procedure.

SUMMARY

Bariatric surgery is a safe and effective treatment for obesity, with a proven track record, and it is the most effective obesity treatment available. More recently, the development of bariatric endoscopic therapies has provided an additional tool that serves as a useful adjunct. Both the bariatric operations and endoscopic procedures involve mechanisms that are restrictive, malabsorptive, and a combination thereof, with subsequent neurohormonal changes that provide both satiety and improvements in metabolic health. In the future, these operations and procedures, as well as their applications, will continue to evolve and be refined as we learn more about the physiology of obesity and its pathophysiologic consequences.

The Role of Pancreatic Development in Human Diabetes, 481

The pancreas provides both the enzymes that digest the food in the gut and the hormones that control utilization of the nutrients supplied by that digested food. Two distinct components of the pancreas, the exocrine and endocrine compartments, accomplish these related tasks. The ductal and acinar cells of the exocrine compartment comprise the majority of the organ, while the islets of Langerhans of the endocrine portion are scattered throughout the exocrine matrix.

During pancreatic development, a common pool of progenitor cells in the early gut endoderm differentiates into these distinct cell types. Positional and temporal cues provided by extracellular signals direct sequential changes in the gene expression program of individual cells and ultimately determine the phenotype of the differentiated cells and the organization of the mature organ. Any breakdown in the orchestration of this complex process of growth, differentiation, migration and organization can damage the mature organ and can cause diabetes by impairing the function of the insulin-producing β cells. An understanding of pancreatic development has provided us with new insights into the causes of diabetes and new strategies for intervening in the disease.

PANCREAS MORPHOGENESIS

During gastrulation, mesendodermal cells that migrate through the node region of the early vertebrate embryo start to segregate to form distinct mesodermal and endodermal germ layers. Endodermal cells aggregate to form a contiguous epithelium that spans the whole length of the forming gastrointestinal tract of the developing embryo. Digestive organs develop along the anterior-posterior and dorsal-ventral axes of this sheet of cells in a precise and predetermined pattern.[1-3]

The pancreas forms from clumps of cells that bud from the dorsal and ventral aspects of the gut endoderm near the foregut/midgut junction[4,5] (Fig. 28.1). Well before any morphologic evidence of the pancreas becomes apparent, interactions between the mesodermally-derived notochord and the endodermal epithelium initiate dorsal pancreas formation.[6] Similarly, interactions between the lateral plate mesoderm and the lateral endoderm ensure proper induction of the ventral pancreas.[7] The first morphological sign of pancreas formation is a thickening of the dorsal endodermal sheet caudal to the stomach anlage. This bud structure continues to grow and initiates contact with the dorsal aorta that has fused in the midline and thus separated the notochord and the endoderm.[8] Subsequently, dorsal mesenchyme replaces the aorta and provides essential signals that stimulate pancreatic epithelial branching and cell differentiation.

Similar tissue interactions guide the development of the two ventral buds. In contrast to the dorsal bud that forms in the midline of the epithelium, the ventral buds are derived from the ventro-lateral edges of the endodermal sheet. Instructive signals provided by the lateral plate mesenchyme initiate ventral pancreas formation, and interactions with smaller blood vessels further support organ growth.[8] One of these ventral buds degenerates, while the other one fuses with the dorsal bud when stomach and gut rotate to form the mature organ. The regulation of this rotation is not well understood, but perturbations lead to malformations in humans, including annular pancreas, wherein a part of the ventral pancreas is mislocalized and can constrict the adjacent duodenum.[9]

Mesenchymal-epithelial interactions are required for proper development of the mature tissue.[10,11] Recent studies indicate that the pancreatic mesenchyme governs not only the expansion of early pancreatic progenitors,[12] but also regulate the proliferation of already differentiated endocrine and exocrine cells towards the end of gestation.[13] However, the epithelial cells start to outgrow the mesenchyme during later stages of development, and few remnants of this tissue remain in the adult pancreas. Epithelial cells branch into the surrounding mesenchyme to form an elaborate duct system that allows transport of exocrine enzymes into the duodenum. Distal cells of the branching epithelium differentiate into clusters of acinar cells that are connected to the duct system via centroacinar cells. Acinar cells are organized as small glands (acini) that produce a variety of digestive enzymes, including amylases, peptidases, nucleases, and lipases.

In contrast to the continuous acinar-duct system, endocrine precursors delaminate from the immature ducts during development and migrate into the surrounding mesenchyme, where they aggregate and organize into islets of Langerhans. These distinct islet cells produce a variety of hormones, including insulin, glucagon, pancreatic polypeptide, somatostatin, and ghrelin, which are secreted directly into the bloodstream and regulate gastrointestinal function and nutrient intake, storage, and utilization. Due to intimate interactions between endocrine cells and blood vessels, islets are highly vascularized, with a highly fenestrated network of blood vessels providing ready access to

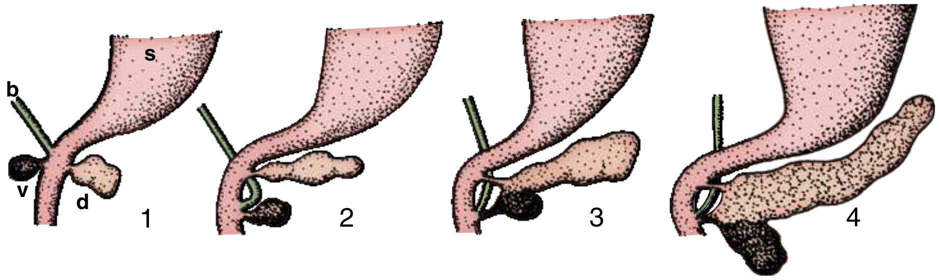

Figure 28.1 Schematic outline of the development of the mammalian pancreas. 1, Dorsal and ventral buds arise from the duodenal part of the primitive gut endoderm *(blackened).* **2,** The dominant ventral bud, following the bile duct, turns and approaches the dorsal bud. **3,** The two buds fuse together. **4,** The ventral bud becomes part of the head of the pancreas (the pancreatic polypeptide–rich duodenal lobe), whereas the dorsal bud gives rise to the body and tail (the glucagon-rich splenic lobe); the pancreatic juice is drained off by the main and accessory pancreatic ducts. *b*, Bile duct; *d*, dorsal bud; *s*, stomach; *v*, ventral bud.

circulating nutrients, signaling molecules, particles, and cells. Similarly, hormone secretion is controlled at least in part by the nervous system; the sympathetic, parasympathetic, and sensory neurons that innervate the islets derive from cells that migrate from the neural crest into the pancreas just as the two buds fuse.[14]

KEY POINTS

- Very early interactions within and between the forming germ layers of the developing embryo pattern the cells that will eventually form the pancreas and initiate the formation of the pancreatic buds.

EARLY ORGAN SPECIFICATION AND BUD FORMATION

Tissue Interaction and Signaling Pathways

With the exception of supporting mesenchyme, blood vessels, and innervating neurons, all mature pancreatic cell types derive from epithelial cells of endodermal origin.[15-17] Several studies have addressed the question of how the pancreas anlage becomes specified within the epithelial sheet that forms the endoderm, and increasing evidence points to a series of tissue interactions as important steps during early stages of organogenesis. During gastrulation, the mesectodermal portion of the embryo signals to the endodermal sheet to establish a prepattern along the anterior-posterior axis.[3]

Although the exact signals required for patterning of the fore-midgut area are not completely understood, studies in mice have implicated the fibroblast growth factor (FGF) signaling pathway in this process.[18] Before any morphologic signs of pancreas formation are apparent, the midline of the endodermal epithelium comes in close contact with the overlying notochord, a mesodermal structure known to regulate organogenesis and cell differentiation in adjacent structures. The notochord provides secreted signaling peptides that are required for initiation of dorsal pancreas organogenesis. Members of the transforming growth factor β (TGF-β) and FGF signaling pathways have been implicated in the notochord-mediated induction of pancreas development. A critical aspect of their activity involves repression of the expression of Sonic hedgehog (Shh), a member of the Hedgehog signaling pathway within the pancreas anlage.[19] Ectopic elevation of Hedgehog signaling at the onset of pancreas formation results in pancreas agenesis, indicating that tight regulation of the activity of this pathway is essential for proper organ formation. However, the notochord provides only permissive signals, because it cannot induce expression of pancreatic markers in nonpancreatic endoderm.[6]

In contrast to the singular dorsal pancreas, two distinct pancreatic buds form within the ventro-lateral endoderm, a region that is not contacted by the notochord. Tissue recombination experiments in chicks and mice demonstrate that similar but distinct signals from the lateral plate mesoderm (LPM) ensure the correct temporal-spatial induction of the ventral pancreas.[7,18] Before it contacts the LPM, no pancreatic markers are detectable in the presumptive ventral pancreas, but LPM or the TGF-β superfamily members activin and morphogenetic proteins (BMPs), as well as retinoic acid (RA), have been shown to induce expression of pancreatic genes in underlying endoderm (see following section).[7] Of note, mesenchyme isolated from the pancreatic region carries the potential to induce pancreatic gene expression in anterior endoderm normally fated to develop into stomach and esophagus. Thus, in contrast to the notochord–endoderm interaction that induces dorsal pancreas development in a permissive fashion, the LPM actively instructs uncommitted endoderm to differentiate into pancreatic tissue. Activin, BMP, and RA signals that mimic the pancreas instructive activity of the LPM are potentially useful in designing a cocktail of growth factors designed to regulate differentiation of uncommitted progenitor cells towards a pancreatic fate.

Other studies have shown that interactions between heart mesenchyme and ventral foregut endoderm regulate differentiation of ventral pancreas and liver progenitor cells.[20] In an analogy to the notochord-dorsal pancreas bud interactions, the septum transversum and heart mesenchyme produce BMP and FGF signals, respectively, that regulate organ differentiation of the ventral endodermal organs, including liver and pancreas. Because of its close proximity, the concentration of FGF ligands produced by the heart mesenchyme is higher at the area fated to develop into liver and lower at the more distal region that develops into ventral pancreas.[20] This is also the case for dorsal pancreatic epithelium, in which low levels of FGF signals have been shown to initiate pancreatic gene expression and block Shh expression, while higher levels of FGF signaling block pancreas induction via increased Hedgehog signaling. Thus, formation of dorsal and ventral pancreatic buds depends on low FGF signals and inhibition of Hedgehog signaling. It is important to note that Hedgehog signaling is active in areas immediately adjacent to the dorsal and ventral buds, thereby establishing a molecular boundary that prevents ectopic expansion of pancreatic tissue beyond its normal borders.

During subsequent stages, the flattened endodermal sheet expands and folds itself to form a tube-like structure. The first morphologic sign of pancreas formation is an epithelial thickening at the dorsal side of the forming gut tube caudal to the stomach anlage, shortly followed by the appearance of two ventral thickenings next to the liver diverticulum. Outgrowth and tissue-specific gene expression continue to depend on cues derived from adjacent tissues. In contrast to earlier stages, mesenchymal signals are now produced from forming blood vessels: the dorsal aorta and smaller vitelline veins that contact the dorsal and ventral buds, respectively.[21] Depletion of blood vessels via explantation in *Xenopus* or via homozygous recombination in transgenic mice that lack the *Flk-1* gene, which encodes a receptor for vascular epithelial growth factor (VEGF), impairs the differentiation of the dorsal pancreatic epithelium.[21,22] Vice versa, ectopic expression of VEGF leads to hypervascularization and islet hyperplasia in pancreatic tissues, as well as ectopic insulin expression in nonpancreatic stomach epithelium, suggesting that VEGF or other molecules secreted by endothelial cells support endocrine cell differentiation. Detailed analysis of the interaction between blood vessels and pancreas buds has revealed physical contact between the aorta and the dorsal bud epithelium, while vitelline veins and ventral bud epithelium are separated by a fine band of mesenchymal cells, although endothelial cells are less critical for ventral bud formation.[22]

Recent results have provided further evidence for the role of signaling molecules in setting up organ boundaries in the pancreas anlage. Studies in zebrafish suggest that Fgf10 expression is critical for separating pancreatic and liver cells in the area of the hepatopancreatic ductal system. Fgf10 is expressed in the mesenchyme surrounding the developing hepatopancreatic duct and functions to restrain inappropriate differentiation of adjacent pancreas into liver cells, as well as liver into pancreatic cells.[23] Thus, secreted signaling molecules are essential in defining the boundaries of the pancreas.

Upon specification of the dorsal and ventral pancreatic anlagen, additional mesenchymal-epithelial interactions contribute to later steps of pancreas organogenesis.[10,11] Splanchnic mesoderm expands medially and surrounds the pancreatic epithelial buds. Signals from the mesenchyme promote epithelial expansion that results in the formation of a branching structure composed of undifferentiated ductal cells. Based on morphologic criteria, Rutter and colleagues argued that the early endodermal cells are "protodifferentiated," and that mature exocrine and endocrine cells appear only after the secondary transition, a process during which the numbers of differentiated acinar and β cells increase significantly.[4,24] More recent studies have shown that early pancreatic mesenchyme generally induces growth and proliferation of epithelial cells, while at later stages mesenchymal signals promote expansion of exocrine and endocrine cells.[13]

KEY POINTS

- A series of signals from adjacent mesoderm and then from overlying mesenchyme first specify the prepancreatic endoderm and then direct the formation, growth, and morphogenesis of the dorsal and lateral pancreatic buds near the foregut/midgut junction.

Induction of the Pancreatic Gene Expression Program

The morphologic changes that occur as pancreas differentiates from gut endoderm depend on sequential changes in gene expression. Extracellular signals provided by tissue interactions between the developing pancreatic endoderm and adjacent tissues ultimately affect cell phenotype by altering gene expression within the nucleus. Recent studies have outlined the underlying molecular events that control these changes in gene expression and have focused in particular on transcription factors (nuclear proteins that control gene transcription) and the epigenetic changes that these factors and other signals induce.

Transcription factors expressed broadly in the endoderm provide competence to respond to the endoderm patterning signals and include early endoderm factors SOX17[25] and RFX6[26]; several transcription factors originally described in the adult liver, such as hepatic nuclear factor HNF1B (a POU-homeodomain factor),[27] forkhead factors FOXA1 and FOXA2,[28] HNF4A (a fatty-acid-binding nuclear receptor),[29-31] and ONECUT1[32,33]; and the zinc finger transcription factors GATA4 and GATA6.[34,35] These genes function in transcriptional hierarchies that not only control endoderm patterning, but also persist in endoderm-derived organs and play roles in the mature pancreas.[36-41] Several of these endoderm factors have also been directly implicated in the control of mature pancreatic gene expression (see Fig. 28.5 and Table 28.1).

The earliest genes selectively expressed in the region destined to become pancreas, the prepancreatic endoderm, are two transcription factors, the parahox homeodomain factor PDX1[42-44] and the basic-helix-loop-helix (bHLH) transcription factor PTF1A.[45,46] PDX1 expression first appears in prepancreatic endoderm more than a day before the initial formation of the dorsal pancreatic bud, and is preceded immediately by the appearance of another parahox factor, MNX1,[47,48] which is expressed more broadly than PDX1 in anterior endoderm. Expression of both MNX1 and PDX1 persists in the initial pancreatic buds, although MNX1 expression is extinguished quickly thereafter, while PDX1 expression lasts a few more days. Expression of both factors is reactivated in mature β cells.

Dorsal, but not ventral, expression of PDX1 depends on MNX1.[47,48] Because MNX1 is also expressed in the notochord during the same period, it is formally possible that MNX1 could control dorsal PDX1 expression via signals from the notochord. PDX1 expression in the dorsal prepancreatic endoderm does not require signals from the notochord, however, suggesting that MNX1 functions cell-intrinsically in inducing PDX1. Extrinsic signals that induce PDX1 expression in the dorsal prepancreatic endoderm have not been identified.[6] On the other hand, as described in the preceding section, signals from the LPM including activin, BMPs, and retinoic acid can induce PDX1 expression in the ventral prepancreatic endoderm.[7]

Studies of the *Pdx1* gene promoter have identified several additional endodermal transcription factors as potential intrinsic regulators of *Pdx1* expression.[49-56] These include members of the HNF1 and FOXA families of transcription factors, Onecut1, the paired homeodomain factor PAX6, and PDX1 itself[49,50,55,57,58] (MNX1 also may act through these same PDX1 binding sites, given its similarity to PDX1 in the DNA-binding homeodomain). HNF1A and PAX6 are not expressed early enough or broadly enough to initiate the early expression of PDX1 in the embryonic gut and pancreatic buds, but the expression patterns of Onecut1, HNF1B, FOXA1, and FOXA2 suggest that they could play this role (Fig. 28.2). Mice lacking Onecut1 have reduced expression of PDX1,[58] and embryoid bodies lacking FOX2 fail to activate the *Pdx1* gene,[55] suggesting that these two factors may be *bona fide* activators of PDX1 expression in the prepancreatic endoderm and pancreatic buds and therefore lie directly upstream of PDX1 in the hierarchy of factors involved in initiating pancreas development (see Fig. 28.5).

PDX1 is required for outgrowth of the pancreatic buds. In mice with targeted disruptions of the *Pdx1* gene, the pancreatic buds fail to branch and expand after initial formation, yielding an animal that lacks a pancreas at birth.[43,44,59] Confirming its role upstream of PDX1 in the endoderm, lack of Onecut1 results in reduced pancreatic size[58], and removal of MNX1 specifically arrests the growth of the dorsal pancreatic bud.[47,48] Homozygous null mutations in the *PDX1* gene, which encodes human PDX1, have been identified in humans born with pancreatic agenesis,[60] and mutations in the zebrafish gene encoding PDX1 also affect pancreas development,[61] reflecting an evolutionary conservation of PDX1 function.

Expression of PTF1A follows shortly after PDX1 and is restricted within the endoderm to the dorsal and ventral pancreatic buds.[62,63]

The aorta induces expression of PTF1A in the dorsal pancreatic bud, but vascular-derived signals do not appear to play as critical a role in its expression in the ventral buds.[22] Although PTF1A was initially described as an exocrine-specific transcription factor,[46,63] in fact it plays an essential role in determining pancreatic cell fate. Although in the mature pancreas its expression is restricted to the acinar cells, in mouse embryos lacking PTF1A, cells normally fated to contribute to both exocrine and endocrine lineages in the pancreas instead revert to duodenal epithelium.[45]

KEY POINTS

- The formation and growth of the pancreatic buds depends on changes in gene expression directed by a set transcription factors initially expressed broadly in the epithelial layer of buds.

CELL TYPE DIFFERENTIATION

Signaling Pathways

Several embryonic signaling pathways regulate distinct aspects of pancreas organogenesis and endocrine cell differentiation. As discussed earlier, the TGF-β, FGF, and Hedgehog signaling pathways coordinate initiation of pancreas formation. After bud formation, these pathways play additional roles in the differentiation of the distinct cell types that form the mature pancreas.

FGF7 and FGF10 are expressed transiently in pancreatic mesenchyme and have been shown to promote proliferation of pancreatic epithelial cells.[12,64] Transgenic mice that carry a homozygous deletion in the *FGF10* gene display severe defects in pancreas morphogenesis that result from loss of PD1-positive pancreatic epithelial progenitor cells.[12] FGF signaling also has been shown to regulate proliferation of endocrine and exocrine cells,[65,66] and expression of a dominant active form of the FGF receptor 2 (FGFR2) inhibits endocrine and exocrine cells.[65-67]

TGF-β/activin signaling has been shown to affect differentially exocrine and endocrine cell differentiation. Treatment of isolated pancreatic buds with soluble TGF-β1 stimulates differentiation of endocrine cells, particularly β cells and pancreatic polypeptide cells.[68] Signaling via activins, a subgroup of TGF-β signaling members, also has been shown to affect preferentially endocrine cell differentiation. Treatment of pancreatic buds with follistatin, an antagonist that physically binds to activins, inhibits endocrine cell differentiation while promoting exocrine cell formation.[69] Transgenic mice ectopically expressing dominant-negative activin type II receptor (dnActRII) develop islet hypoplasia, a phenotype also observed in mice carrying targeted mutations in both ActRIIA and ActRIIB.[70-72] More recent work has focused on the downstream TGF-β/activin signaling cascade of. Ligand binding to their respective receptors on receiving cells results in the phosphorylation of receptor associated Sma- and Mad-related proteins 1, 2, 3, 5, and 8 (R-Smads). Another Smad, Smad4, acts as a universal partner for the R-Smads, and the R-Smad/Smad4 complex interacts with distinct DNA-binding factors to regulate target gene transcription. Surprisingly, loss of Smad4 has no appreciable effects on pancreas formation,[73,74] suggesting Smad4-independent TGF-β/activin functions. Additional support for the TGF-β/activin requirement during pancreas development comes from studies in which Smad7, a negative factor that interferes with Smad–receptor and Smad–Smad interactions, is ectopically expressed in pancreatic tissue. Embryonic expression of Smad7 in pancreatic epithelium results in pancreas and β cell hypoplasia.[75] Of note, ectopic expression of Smad7 specifically in adult pancreatic PDX1+-cells resulted in hypoinsulinemia followed by diabetes.

The role of Hedgehog signaling during endocrine cell differentiation is less clear. At early stages, elevation of Hedgehog signaling in the pancreas anlage results in transformation of the pancreatic mesenchyme into duodenal mesoderm.[19,76] Increased signaling impairs pancreatic organogenesis, at least in part, because signals normally provided by the pancreatic mesenchyme are reduced. Also, as has been shown for other organs, ectopic activation of Hedgehog signaling reduces FGF10 expression, which is known to promote pancreatic epithelial and endocrine cell expansion.[77,78] By contrast, a low level of Hedgehog signaling is detected throughout pancreas organogenesis and in mature islets.[79,80] In addition, cell culture experiments have revealed that Hedgehog signaling activates the *Pdx1* and insulin gene promoters in cultured insulinoma cells,[81,82] suggesting a different and potentially important role for the pathway in maintaining mature β cell function. Elimination of Smoothened, a critical component of the Hedgehog signaling cascade, in pancreatic epithelial cells revealed a requirement of the pathway during embryonic β cell formation. While β cell numbers were restored by birth, studies on adult transgenic animals showed defects in insulin production and glucose intolerance.[79] Intriguingly, similar defects in β cell function were observed in transgenic mice with overactive Hedgehog signaling,[83] suggesting that perfectly balancing the output of this signaling cascade is critical for maintenance of normal β cell function.

Hedgehog signaling shares many features with another embryonic pathway, the canonical Wnt cascade. Several Wnt ligands and their respective Frizzled receptors have been identified in embryonic and adult pancreas.[84,85] Functional studies in which dominant-negative receptors were expressed ectopically, or β-catenin, an essential component of the canonical Wnt signaling cascade, was eliminated, have pointed to an important role of this pathway during embryonic pancreas formation; however, its exact functions in specific pancreas cell types remains under debate. Although several studies found a requirement for canonical Wnt signaling during exocrine development,[86-88] others have noted a role for β-catenin in endocrine function.[89] Ectopic activation of β-catenin signaling results in different phenotypes, depending on the time of expression. Activation at the onset of pancreas formation blocks progenitor cell expansion, while later expression results in a profound increase in acinar cell numbers.[90] A recent study analyzing the requirement for the mouse homolog of Pygopus, Pygo2, a necessary nuclear component of the Wnt cascade, revealed a novel role for Wnt signaling in early pancreatic mesenchyme.[91] According to this study, mesenchymal mPygo2 is essential in regulating epithelial progenitor proliferation, including endocrine progenitors. Thus, Wnt signaling regulates pancreas formation at various stages in both mesenchyme and epithelium. Furthermore, studies in adult animals indicate a role for canonical Wnt signaling in adult β cell proliferation.[92]

In addition to the TGF-β, FGF, Hedgehog, and Wnt signaling pathways, Notch signaling contributes to cell fate choices and differentiation in the pancreas, as it does in many other organs during embryogenesis. Notch signaling commonly regulates cell fate decision via a process known as lateral inhibition, in which a given cell within a homogenous field of cells becomes less susceptible to ligand-activated Notch signaling. As a consequence, this cell initiates a specific differentiation program while continuing to provide Notch ligands to adjacent cells, thereby blocking the differentiation of its neighbors (Fig. 28.3).[93] A similar mechanism regulates the differentiation of endocrine cells during pancreas development. Reduction of Notch pathway activity in transgenic mice lacking essential Notch signaling components results in upregulation of expression of Neurogenin3 (NEUROG3), a bHLH transcription factor required for endocrine formation[94] (see following section), and precocious endocrine differentiation.[95,96]

More recent studies have provided an even more nuanced view of Notch activity during endocrine progenitor formation. Studies by Shih and colleagues describe how intermediate levels of Notch signaling activate expression of Sox9, which in turn activates Ngn3 expression. In contrast, high levels of Notch activate both Sox9 and Hes1 expression and thereby promote formation of duct progenitors within the trunk region of the forming epithelial network.[97] The key findings from this work establish Notch as a critical determinant in both endocrine and duct fate development.

Other studies have revealed roles for Notch signaling in other steps of pancreatic formation, both before and after its well-recognized role in regulating endocrine specification. Even before pancreas is specified, Notch signaling in the foregut endoderm helps to define the area of the pancreas domain.[98] Ectopic expression of a constitutively-active, truncated form of the Notch1 receptor at the onset of pancreas formation blocks both exocrine and endocrine cell differentiation, suggesting that Notch signaling normally may allow the expansion of undifferentiated precursor cells.[99-101] After endocrine specification, constitutive activation of Notch signaling also blocks endocrine cell differentiation in endocrine precursor cells and can change the differentiation potential of some α/β cells away from the endocrine phenotype toward the ductal fate.[102] By contrast, Notch activation in fully matured endocrine cells is not sufficient to change their differentiation status.

Evidence from mouse development suggests that FGF signaling moderates Notch activity during pancreas formation. Ectopic expression in the pancreas epithelium of FGF10, an FGF ligand normally found in pancreatic mesenchyme, activates expression of Notch ligands and receptors and the Notch target gene *HES1*.[103,104] Given the evidence of interactions between embryonic signaling pathways during the formation of other organs, it will be critical to determine how these exchanges regulate pancreas development and pancreas cell differentiation.

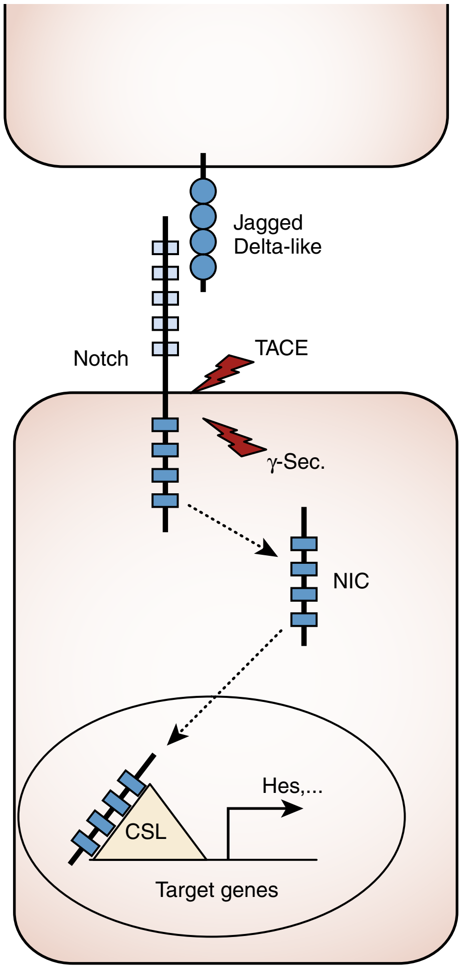

Figure 28.3 **Notch signaling pathway.** Binding of Jagged/Delta-like ligands to Notch receptors activates the Notch signaling cascade. Two proteolytic events mediated by the tumor necrosis factor-α-converting enzyme (TACE) and γ-secretase (γ-Sec.) enzymes result in the generation of an intracellular Notch fragment (NIC) that translocates from the membrane to the nucleus. Interaction with transcription factors from the CSL (CBF1/suppressor of hairless/Lag-1) family activates transcription of Notch target genes, including *HES* genes known to block the transcription of Neurog3.

KEY POINTS

- As the pancreatic buds start to grow, local signaling events direct the initially uniform clusters of epithelial cells to differentiate toward the endocrine and exocrine cell lineages that will eventually populate the mature pancreas.

Transcription Factors

The target of Notch inhibition in the embryonic pancreas, bHLH transcription factor NEUROG3, functions as a proendocrine factor: it is sufficient by itself to drive precursor cells to an endocrine fate.[95,105] When expressed broadly in the developing pancreatic bud, NEUROG3 can force all of the cells in the developing pancreas to differentiate prematurely into islet cells. NEUROG3 is expressed abundantly but transiently in the developing pancreas in scattered ductal cells and occasional periductal cells, but it is never found at similar levels in mature, hormone-producing cells. Together, these data support a model in which NEUROG3 acts upstream of other islet differentiation

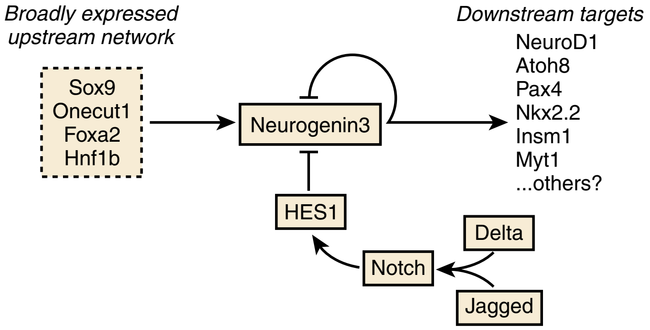

Figure 28.4 **Control of Neurog3 expression.** A model is shown for the positive and negative regulation of Neurog3 expression in pancreatic endocrine progenitor cells.

factors, initiating the differentiation of endocrine cells but switching off prior to final differentiation. This conclusion is supported by the observation that mice homozygous for a targeted disruption of the *Neurog3* gene fail to form any α, β, or δ cells in the pancreas and do not express most of the other islet differentiation factors,[94] as well as by lineage tracing experiments.[106]

Although Notch signaling restricts NEUROG3 to scattered cells within the pancreatic epithelium, additional positive signals are required to initiate NEUROG3 expression in the absence of Notch signaling. Studies of the *NEUROG3* gene promoter implicate several transcription factors in this role, including HNF1, FOXA, ONECUT1, and SOX9,[107-110] which function together as an interacting network[109] (Fig. 28.4). Roles for ONECUT1 and SOX9 have been confirmed *in vivo*.[108,110]

Because NEUROG3 initiates, but does not complete, islet differentiation, it must induce a set of factors that complete the tasks of islet cell differentiation, that is, determination and differentiation of islet cell subtype, formation and organization of islets, and function of the mature islet cells. Several direct targets of NEUROG3 have been identified, including the genes encoding the bHLH factors NEUROD1 and ATOH8, the zinc finger factors MYT1 and INSM1, the paired-homeodomain factor PAX4, and the homeodomain factor NKX2.2.

NEUROD1 expression initiates slightly later than NEUROG3 during pancreatic development; but, unlike NEUROG3, it persists in the mature islet cells, where it plays a role in the expression of a number of differentiated endocrine cell products including insulin.[111-114] NEUROG3 can bind to and activate the *NeuroD1* gene promoter, and it can induce NEUROD1 expression in *Xenopus* embryos[115] and pancreatic ductal cells.[116,117] Conversely, NEUROG3-null embryos completely lack NEUROD1 expression in the pancreas,[94] while NEUROG3 expression is unchanged in NEUROD1-null embryos[105]. Expression of the distantly related bHLH factor ATOH8 and the zinc finger factors MYT1 and INSM1 also is activated by NEUROG3, and ATOH8 and INSM1 appear to play a role in feedback regulation of NEUROG3 expression.[118-120] In addition, MYT1 expression persists in the differentiated endocrine cells and may play a role in their maturation.[121]

Just as it can with the *Neurod1* gene promoter, NEUROG3 binds to and activates the *Pax4* gene promoter[122]; it can activate the intact gene in cultured cells[117,123]; and in its absence PAX4 expression is lost in the pancreas.[94] In addition, studies of the *Pax4* gene promoter implicate the more broadly expressed endoderm factors HNF1B and HNF4A along with NEUROG3 in cooperative activation of PAX4 expression.[122,123] In the case of the gene encoding NKX2.2, NEUROG3 binds to and activates one of three alternate promoters in the gene and cooperates with FOXA transcription factors in activating the gene.[124]

Unlike NEUROD1, ATOH8, and MYT1, however, PAX4 and NKX2.2 expression are not induced in all islet lineages. PAX4, therefore, falls into a class of factors that play specific roles in the differentiation of the different islet cell subtypes. These factors can be grouped into the early group, factors like PAX4 and the NK homeodomain factors NKX2.2[125] and NKX6.1[126] that are coexpressed with NEUROG3 in endocrine progenitor cells,[105] and the late group, genes like the basic leucine zipper transcription factor *MAFA*,[127] *PDX1* and *RFX6* (both in a second phase of their expression), *PAX6*,[128,129] and the paired-related homeodomain transcription factor *ARX*,[130] that are expressed at the final stage of differentiation and are largely restricted to differentiated islet cells (Table 28.1). It is not clear whether any of these factors can actually determine the cell-type fate of the cell in which they are expressed, or if they simply complete the differentiation process initiated by other gene products and signals.

Once NEUROG3 is expressed in an appropriate progenitor, that cell is destined to become an islet cell, but the decision as to which of the four islet cell types it will become apparently is controlled by other factors. Ectopic broad expression of NEUROG3 in the developing pancreatic bud causes uniform and precocious endocrine differentiation, but the type of endocrine cell depends on when NEUROG3 is induced: early expression of NEUROG3 produces α cells,[95,105] but later expression of NEUROG3 produces other cell types.[127] It can be hypothesized, therefore, that the cell-intrinsic competence of the progenitor cells to generate different islet cell types changes over time, or that extracellular signals that change with time guide the differentiation of the NEUROG3-expressing cells into the different islet cell types. The identities of the signals or factors that determine individual islet subtype fates remain to be determined.

KEY POINTS

- The differentiation of exocrine and endocrine cells and their subsequent differentiation into sublineages depend on the action of a cascade of lineage-specific transcription factors.

Islet Formation

Endocrine cell differentiation, including insulin- and glucagon-positive cells, can be detected shortly after the pancreatic buds form, but these cells are immature and do not contribute to the mature islets. Mature β cells form during the secondary transition at approximately embryonic day 13 to 14 in the mouse. At this time endocrine precursor cells leave the endodermal epithelium and migrate through the adjacent extracellular matrix (ECM) into the surrounding mesenchyme.

Cell culture assays have implicated matrix metalloproteinases in this process, although experimental evidence from *in vivo* studies supporting these results is currently missing.[131] Cell attachment to and migration via the ECM is mediated by integrins, heterodimeric transmembrane proteins that serve as extracellular matrix receptors.[132] Functional evidence for an essential role of integrins during migration of islet precursors comes from *in vivo* studies in which islet formation in human fetal pancreas transplanted under the kidney capsule of recipient mice was inhibited by injection of integrin-blocking peptides.[133] The integrin family comprises a large number of different members with distinct substrate specificities, and fetal and mature human β cells express different repertoires of integrins.[134] Changes in integrin composition may explain why fetal β cells are more motile than their adult counterparts, a difference that also may provide insight into the molecular mechanisms that prevent dispersion of endocrine cells once mature islet structures have formed.

Nonetheless, a number of open questions remain with regard to the regulation of islet progenitor migration and islet formation. For example, studies using transgenic animals have shown that a given

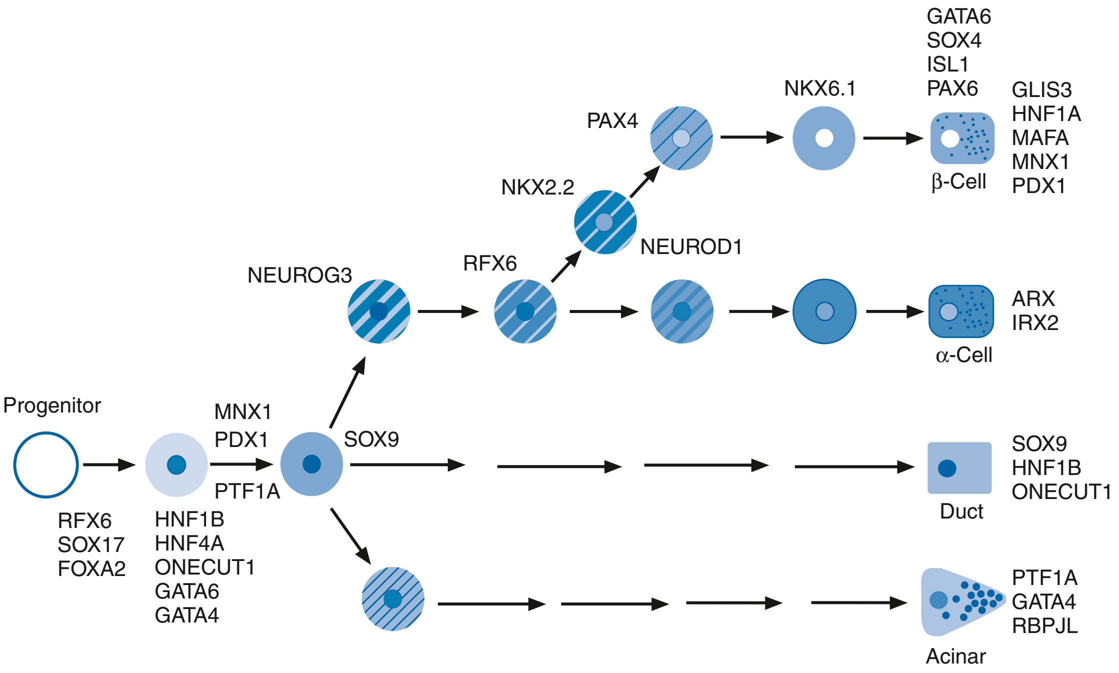

Figure 28.5 A simplified model for the role of islet transcription factors in endocrine differentiation in the developing pancreas. The proposed position for each transcription factor is based on its timing of expression, timing of predominant functional role, or both. Clearly, some factors function at multiple steps, but only key steps are shown for simplicity.

islet originates from several independent endocrine precursors.[135] Thus, endocrine cells delaminating from the ductal structures during embryogenesis must follow a specific guiding mechanism that coordinates their migration path toward a specific location. Although cell migration has been well studied in neural cells that respond to attractive and repulsive guidance cues, a putative, localized source of chemoattractant molecules that stimulate islet precursor migration has not been identified. Furthermore, evidence from studies in human patients with diabetes suggests neogenesis of endocrine cells throughout life.[136] Although still controversial, some endocrine cells appear to form away from already existing islets, raising the question whether these cells migrate toward already formed islets or cluster with other newly formed endocrine cells to initiate aggregation of a new islet. In either case, it is likely that specific, as yet unidentified, guidance mechanisms control these processes.

KEY POINTS

- As cells of the endocrine lineage start to differentiate in the forming pancreas, the new endocrine cells delineate from the forming ducts and begin to form clusters that eventually develop into the islets of Langerhans, which comprise the endocrine compartment of the mature pancreas.

THE ROLE OF PANCREATIC DEVELOPMENT IN HUMAN DIABETES

One beneficial consequence of our improving understanding of pancreatic islet development has been new insights into human diabetes. Short-term energy balance and the control of plasma glucose levels depend on the ability of the β cells to sense changes in nutrient status and respond with appropriate insulin production and secretion. This fine-tuned capability develops along with morphologic development of the islets, and depends on an adequate number of β cells with precisely functioning gene expression programs placed in the appropriate local environment. Any flaws in pancreatic islet development, therefore, can potentially lead to impaired insulin secretion and diabetes.

As a consequence, it is not surprising that mutations in a number of human genes involved in pancreatic islet development, especially genes encoding transcription factors, can lead to diabetes (see Table 28.1). Heterozygous mutations in transcription factors shown in Fig. 28.5 account for five of the first six genes identified that cause maturity onset diabetes of the young,[41,137-141] an autosomal recessive form of diabetes that usually first presents in children and young adults. In addition, mutations in the genes encoding ISL1 and PAX4 have been implicated in families with later-onset diabetes,[141,142] and heterozygous mutations in *GATA4* and *GATA6* and homozygous mutations in *RFX6, MNX1, PDX1, PTF1A, NEUROD1, NKX2.2*, and *PAX6* have been identified in patients with neonatal diabetes.[143-145] Interestingly, although homozygous mutations of the gene encoding NEUROG3 cause neonatal diabetes in mice, humans with homozygous null mutations of the *NEUROG3* gene still generate a reduced number of islet cells and have a later-onset form of diabetes, showing that NEUROG3 is not absolutely required for the islet cell differentiation in humans.[146] Analysis of these mutations has provided insight into the process by which β cell dysfunction may lead to the development of diabetes in humans.

KEY POINTS

- Insights into the process of pancreas and islet development have led to the identification of multiple developmental genes, especially genes encoding transcription factors, that can cause human diabetes when mutated, leading to new insights both into the development of the human pancreas and into the causes of human diabetes.

  Glucagon-Like Peptide-1 Secretion and Signaling, 494

INTRODUCTION

Glucose concentrations are tightly regulated in the fasting and postprandial state by the actions of two hormones with opposing actions. Insulin secretion is stimulated by rising glucose concentrations and suppressed by low glucose concentrations. Signaling through its cognate receptor, it stimulates glucose, fat, and amino acid uptake by insulin-sensitive organs while suppressing endogenous glucose production, release of free fatty acids, and protein catabolism.

On the other hand, glucagon secretion is stimulated by hypoglycemia and results in stimulation of endogenous glucose production. As such it is a key counterregulatory hormone. Abnormalities in the secretion and signaling of both hormones play important roles in the pathogenesis of type 2 diabetes. Understanding their regulation, synthesis, and secretion, as well as their interactions, is key to understanding diabetes.

In addition, there are other novel aspects that may be important in health and disease. Glucagon is an important insulin secretagogue and may help potentiate insulin secretion *in vivo*. More importantly, this signaling may occur through a receptor for glucagon-like peptide (GLP)-1 present on β cells. GLP-1 is a product of proglucagon processing that also may have actions of relevance to the regulation of metabolism. These topics will be considered in turn in this chapter.

HORMONAL SYNTHESIS

Insulin

Insulin is synthesized in the β cell as preproinsulin, a polypeptide comprising (in sequential order) a signal peptide, the B domain, a C domain flanked by dibasic cleavage sites, and the A domain (Fig. 29.1). During and after translation, preproinsulin is transported to the endoplasmic reticulum, where the signal peptidase cleaves the signal peptide, transforming preproinsulin to proinsulin. Proinsulin then folds, forming three highly conserved disulfide bonds into a heterodimer linked by the C domain, which is cleaved off during the transition from endoplasmic reticulum to the Golgi complex and secretory granules. The mature secretory granules contain insulin and C-peptide, which are secreted in a 1:1 ratio.

The proteolytic cleavages required for the conversion of proinsulin to insulin are catalyzed by the prohormone convertases (PCs)—both PC-1/3 and PC-2 are required, although PC-2 preferentially cleaves the C-peptide/A chain junction, while PC-1/3 cleaves the B chain/C-peptide junction.[1] Work by Rhodes et al. has suggested that PC-2 follows the action of PC-1/3 and facilitates formation of mature insulin granules.[2] The accumulation and secretion of proinsulin in diabetes may reflect acquired defects in these enzymes, or a relative deficiency, although their expression rises in the presence of hyperglycemia.[3] At present there is no evidence that common genetic variation in the prohormone convertases is associated with predisposition to diabetes.[4]

Mutations that affect protein folding (for example loss of the cysteine residues forming the disulfide bonds B7-A7, B19-A20, and A6-A11) lead to the accumulation of misfolded insulin and resultant endoplasmic reticulum stress, which ultimately lead to β cell dysfunction and loss. Common genetic variation in the enzymes mediating insulin synthesis or regulating the environment within the endoplasmic reticulum will also increase misfolding and predispose to secretory dysfunction.[5-7] Zinc accumulates within the β cell, specifically in the insulin secretory granule, where it may stabilize insulin into hexamers. A genetic variant in the zinc transporter is associated with type 2 diabetes.[8]

Insulin secretion is triggered by glucose concentrations above a threshold, but synthesis occurs at lower concentrations. This implies that even at normal physiologic concentrations, insulin stores are being replenished. Insulin synthesis occupies 10% to 50% of the protein synthetic activity of the β cell. Consequently, the complex sequence of transcription, translation, and posttranslational modification is very susceptible to stressors such as caloric excess or impaired insulin signaling.[9,10] Pancreas/duodenum homeobox protein 1 (PDX-1) and V-maf musculoaponeurotic fibrosarcoma oncogene homolog A (MafA) are two of the most prominently studied regulators of insulin gene expression, both of which are essential for normal insulin gene expression.[11,12] Both of these transcription factors are in activated by hyperglycemia, but they both can be deactivated when hyperglycemia is chronic and become integral parts of the manifestations of glucose toxicity and accompanying oxidative stress (see Chapter 38). The mechanism for loss of PDX-1 is posttranscriptional,[13,14] whereas the loss of MafA is posttranslational.[15,16]

β cell stress (*in vitro*),[5] type 2 diabetes,[17] and impaired glucose tolerance increase proinsulin concentrations in the circulation, together with an accompanying decrease in insulin secretion. The proinsulin/insulin ratio in the peripheral circulation has been proposed as a marker of β cell health,[18,19] but this has significant limitations:

Fig. 29.1 Insulin Synthesis from Preproinsulin. (Modified from Sun J, Cui J, He Q. Proinsulin misfolding and endoplasmic reticulum stress during the development and progression of diabetes. *Mol Aspects Med*. 2015;42:105–118.)

proinsulin has a longer half-life (20–30 min)[20] than insulin (~5 min) and, unlike insulin, is not extracted by the liver.[21,22] This limitation can be overcome only by direct and simultaneous measurement of insulin and proinsulin secretion.[19,23] It remains to be ascertained if increased proinsulin concentrations in the peripheral circulation reflect endoplasmic reticulum stress and can be used to predict future decline in β cell function and glucose tolerance.

KEY POINTS

- Insulin is synthesized as preproinsulin, a polypeptide that, after translation, is processed by the endoplasmic reticulum to the mature folded protein. This process is subject to misfolding and under conditions of high demand may produce endoplasmic reticulum stress and secretory dysfunction.

Glucagon

Glucagon is a product of the *GCG* (glucagon) gene, which is strongly conserved across vertebrate species and is expressed in pancreatic α cells, in intestinal enteroendocrine cells, and in some neurons (chiefly within the brainstem). The gene is transcribed and translated to proglucagon, which is then cleaved by the two prohormone convertases, described above, that are differentially expressed in specific tissues (Fig. 29.2). PC-1/3 is mainly expressed in intestinal enteroendocrine cells and cleaves proglucagon to form oxyntomodulin, GLP-1, and GLP-2, amongst other peptide products. On the other hand, PC-2 is expressed in the α cell, and the predominant product of proglucagon cleavage is glucagon.[24]

The selective expression of PC-1/3 and PC-2 may not be absolute, and there are circumstances where PC-2 may be expressed outside of the islet, leading to intestinal synthesis and secretion of glucagon. In multiple animal models exposed to stressors such as overfeeding, there is evidence of inducible expression of PC-1/3 within the islet and subsequent intraislet secretion of GLP-1. For example, interleukin 6,[25] hyperglycemia,[26] and free fatty acids[27] seem to increase PC-1/3 expression in islets. Whether this is of any relevance to humans in health and disease remains unclear, but will be discussed.

Glucagon Synthesis in the Enteroendocrine Cell. The suggestion that extrapancreatic synthesis and secretion of glucagon might occur is not novel,[28] with multiple conflicting reports in the literature.[29] Definitive conclusions have been hampered by the sensitivity and specificity of the assays used to measure glucagon. PC-2 may be expressed in some enteroendocrine cells, and Lund et al. demonstrated the presence of intact glucagon in the sera of patients who had undergone total pancreatectomy.[30] In this instance glucagon was measured using both a mass spectrometry–based method as well as a sandwich enzyme-linked immunosorbent assay targeting both the N- and C-terminal regions of glucagon. Whether this intestinal production of glucagon is significant in humans who exhibit "paradoxical" postprandial rises in glucagon after intestinal surgery and retain their pancreas[31] remains to be ascertained.

KEY POINTS

- Glucagon arises from the posttranslational processing of proglucagon by prohormone convertase enzymes. The selective expression of prohormone convertase-2 vs. prohormone convertase-1/3 determines the final cleavage product of proglucagon.

HORMONAL SECRETION AND ACTION

Insulin

Stimulators. When an intravenous glucose challenge is used to stimulate β cell function, insulin consisting of preformed and docked insulin granules is released into the circulation and peaks 3 to 5 minutes after the injection. This is referred to as the acute insulin response or first phase of insulin secretion (Fig. 29.3).[32-34] The second phase of insulin secretion occurs over the next hour (depending on whether stimulation is transient[25] or sustained[26]). Other agents used to stimulate insulin secretion include glucagon,[35] secretin,[36] and the beta adrenergic stimulator isoproterenol.[37,38] Probably the commonest function test utilized is the oral glucose tolerance test—usually the 75-g glucose test, which has been used to characterize glucose tolerance status in prediabetic individuals (Fig. 29.4). With appropriate sampling frequency, this test can be used to reliably measure insulin secretion.[39] Mixed meal tests also use an oral challenge containing carbohydrate, fat, and protein. However, these are less standardized and may differ in terms of whether a liquid or a solid challenge is used. Their advantage is that they can be more easily utilized for tracer-based measurements of glucose metabolism.[40]

Somewhat counterintuitively, insulin concentrations should not be used to measure insulin secretion *per se*. This is because insulin concentrations represent the end result of insulin secretion by the β cells into the portal circulation, where variable hepatic extraction of insulin occurs prior to insulin reaching the systemic circulation.[41] Whether hepatic extraction is a passive or active process remains to be ascertained.[42] However, the magnitude of extraction seems to be related to insulin secretion, so that in health as much as 50% of insulin in the portal circulation does not reach the systemic circulation. To date, with one exception,[43] there is no clear evidence that differences in hepatic extraction can contribute to how individuals respond to a glucose challenge. Given the confounding effects of variable hepatic insulin extraction on measures of β cell function using insulin concentrations, C-peptide (which does not undergo hepatic extraction and is secreted in a 1:1 ratio with insulin) has been utilized. Because C-peptide has a longer half-life (~35 min) than insulin and will therefore accumulate in the circulation, knowledge of its kinetics will enable deconvolution of the insulin secretion rate. The use of a population model for C-peptide kinetics has been validated and avoids the need for individually determining C-peptide clearance in subjects with intact renal function.[44]

A research tool termed *glucose potentiation of arginine-induced insulin secretion* uses insulin responses to both glucose and arginine to estimate insulin secretory reserve.[45] This consists of measuring a baseline insulin response to an intravenous injection of 5 g arginine that is followed by infusion of intravenous glucose for 60 minutes and then with a repeat of the arginine injection (Fig. 29.5). The calculation of *insulin secretory reserve* is made by subtracting the magnitude of the insulin response to the first arginine injection from the response to the second arginine injection. The validation of this tool lies in the close correlation of insulin secretory reserve data to the known quantity of pancreatic islets transplanted into humans,[46] thus allowing this metabolic test to be used as a functional measure of beta cell mass (see Chapter 43).

Mechanisms regulating β cell secretion. High glucose concentrations enter β cells via glucokinase activity[47] and elicit electrical activity by closing adenosine triphosphate (ATP)-sensitive potassium (K^+) channels (Fig. 29.6). These channels consist of four pore-forming subunits (Kir6.2, encoded by *KCNJ11*) and four regulatory subunits (the sulfonylurea receptor SUR1, encoded by *ABCC8*). Intracellular ATP binds Kir6.2 to cause channel closure and depolarization. Drugs that bind to SUR1 can impair insulin secretion (e.g., diazoxide) by opening the channel, while drugs that cause channel closure (e.g., sulfonylureas such as glipizide) stimulate insulin secretion.[9] Gain-of-function mutations in *KCNJ11* or in *ABCC8* will cause neonatal diabetes, while loss-of-function mutations result in congenital hyperinsulinism. Common genetic variation in *KCNJ11* is associated with risk of type 2 diabetes.[48,49]

Membrane depolarization triggers the activation of voltage-gated calcium (Ca^{2+}) channels, and the subsequent influx of Ca^{2+} initiates Ca^{2+}-dependent exocytosis of insulin granules.[9] When exposed to glucose concentrations in the physiologic range, the electrical activity of β cells is characterized by a pulsatile pattern of secretion in which the pulse interval decreases and the pulse amplitude increases as glucose concentrations rise.[50] A rise in Ca^{2+} concentrations through L-type channels drives closure of Ca^{2+}-activated K^+ channels. ATP consumption by Ca^{2+}-ATPases partially reopen K^+ channels for repolarization, which causes cessation of insulin secretion.[51]

It is important to note that the response to a change in glucose concentrations occurs on a background of pulsatile insulin secretion with isolated oscillations having a periodicity of around 5 minutes. They are likely driven by fluctuations in intracellular calcium concentrations and metabolism.[52] Glycolytic oscillations can themselves drive fluctuations in the intracellular ATP/adenosine diphosphate (ADP) ratio, and change in calcium concentrations *per se* can also drive changes in metabolism and energy generation.

Ideally, insulin secretion is expressed as a function of the prevailing insulin action. This requires the use of a minimal model that uses the relationship between changing glucose and C-peptide concentrations and the relationship of changing glucose and insulin concentrations

Fig. 29.6 **The Potassium Channel and its Central Role in Insulin Secretion.** Insulin secretion is inhibited at low glucose concentrations *(left panel)* and stimulated at high glucose levels *(right panel)*. At 5 mM glucose, K_{ATP} channels are active because of the low intracellular ATP/ADP ratio, which keeps the membrane hyperpolarized and prevents electrical activity. At 10 mM glucose, via stimulation of glucose metabolism, the intracellular ATP/ADP ratio increases, resulting in a reduced K^+ current. When K^+ channel activity is sufficiently low, the membrane depolarizes, initiating electrical activity and Ca^{2+} influx. Elevation of intracellular Ca^{2+} activates ATP-consuming Ca^{2+} pumps, causing a fall in the ATP/ADP ratio, reactivation of K^+ channels, membrane repolarization, and temporary termination of electrical activity. Elevated intracellular Ca^{2+} also opens Ca^{2+}-activated K^+ channels, which contributes to the membrane repolarization (not shown). In the hyperpolarized state, Ca^{2+} influx ceases, intracellular Ca^{2+} returns to basal levels, ATP consumption falls, the ATP/ADP ratio is restored, K^+ channels close, and electrical activity is reinitiated. *ATP,* Adenosine triphosphate; *ADP,* adenosine diphosphate; *Ca^{2+}*, calcium; *K^+*, potassium. to calculate these indices. The product—the disposition index—represents the hyperbolic relationship between insulin secretion and action and can be used to measure response to intervention or weight loss or to predict incident diabetes.[53]

Insulin signaling. See Chapter 33.

KEY POINTS

- Insulin is secreted in a 1:1 ratio with C-peptide into the portal circulation. However, insulin undergoes hepatic extraction so that the insulin appearing in the systemic circulation represents the sum of two processes: insulin secretion and hepatic extraction. Because of this, the rate of appearance of C-peptide (which does not undergo hepatic extraction) in the systemic circulation is a more reliable measure of insulin secretion. The primary regulator of insulin secretion is glucose, but other substances such as amino acids and beta adrenergic stimulation can also stimulate insulin release. Glucose also potentiates insulin secretory responses to arginine and glucagon.

Inhibitors. Stimulation of insulin secretion is negatively modulated by the actions of a group of three substances whose function is mediated by negative regulatory G proteins: somatostatin, epinephrine, and prostaglandin E (Figs. 29.7, 29.8, and 29.9). Somatostatin is produced by delta cells within the islet and thought to have the paracrine effect of negatively modulating glucose-induced insulin release.[54] Epinephrine and norepinephrine have a similar negatively modulatory effects whether they are released from islet sympathetic nerve terminals (norepinephrine) or arrive to the islet via the general circulation from the adrenal medulla (epinephrine).[55] It has been well documented that, during clinical stress states such as surgical procedures and extensive body burns, adrenergic inputs to the islet diminish insulin secretion, stimulating hepatic glucose production and thereby causing hyperglycemia. Prostaglandin E is synthesized by the islet via the arachidonic acid cascade and has specific binding sites on islet plasma membranes. It is ideally located to negatively modulate glucose-induced insulin secretion.[56-58] Sodium salicylate, an inhibitor of cyclooxygenase and prostaglandin E synthesis, has been shown to augment glucose-induced insulin secretion *in vitro* and *in vivo* in diabetic humans (Fig. 29.10).[58]

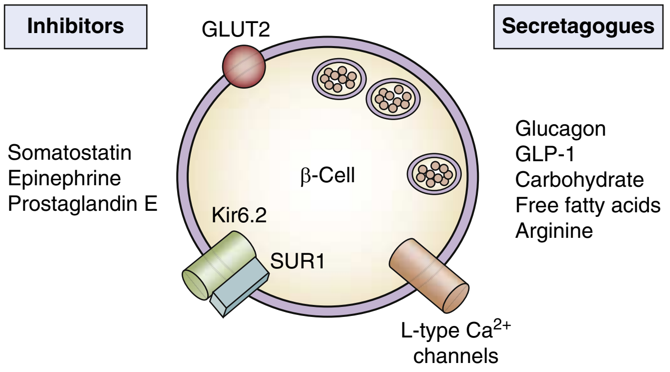

Fig. 29.7 **Regulation of Insulin Secretion.** *GLP,* Glucagon-like peptide; *Ca^{2+}*, calcium.

Glucagon

Stimulators: Glucagon provides the first and most important line of defense against hypoglycemia. When blood glucose levels reach the 65 to 68 mg/dL range,[59] usually because of exogenous insulin injections or purposefully during insulin tolerance tests or hypoglycemic clamps, glucagon is immediately released from α cells into the hepatic portal system (Figs. 29.11 and 29.12). The mechanism of the glucagon release is related to a switching off the physiological suppressive effect that insulin and/or zinc bound to insulin has on glucagon secretion.[60-62] When glucagon reaches the hepatocytes, it stimulates glycogenolysis, and glucose is released into the systemic circulation to correct systemic

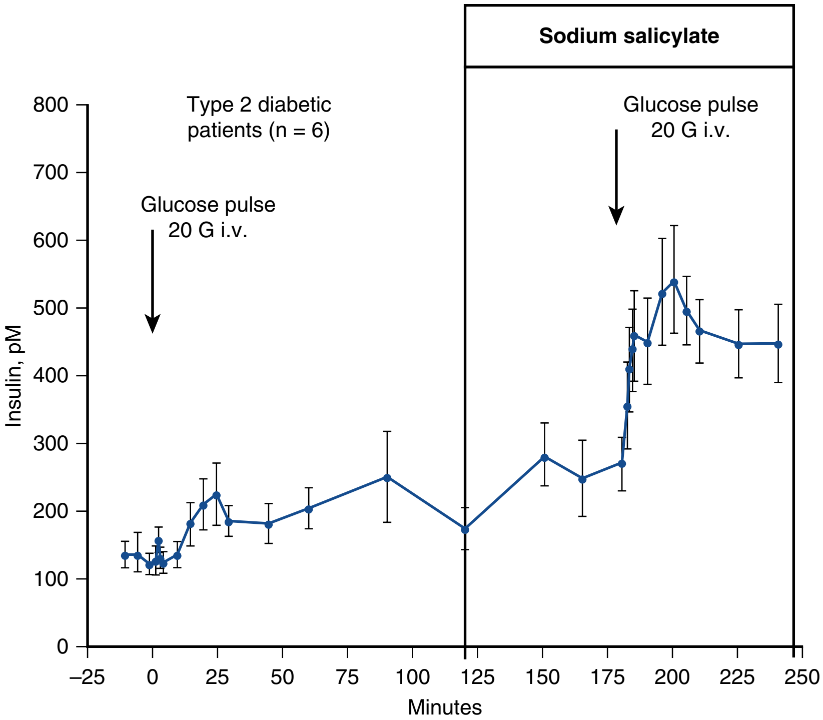

Fig. 29.8 Inhibition of prostaglandin synthesis by salicylate increases the secretion of insulin in response to an intravenous glucose challenge in subjects with type 2 diabetes. (Modified from Robertson RP, Chen M. A role for prostaglandin E in defective insulin secretion and carbohydrate intolerance in diabetes mellitus. *J Clin Invest*. 1977;60:747–753.)

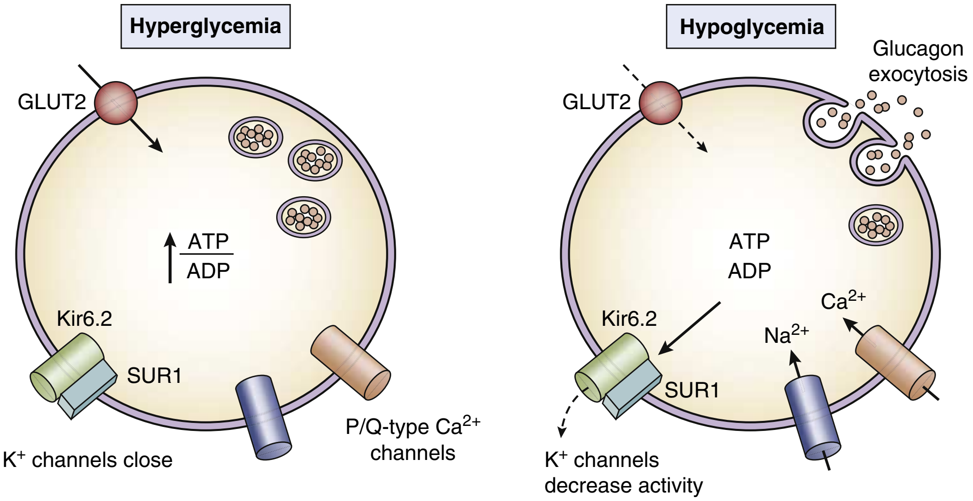

Fig. 29.9 Unlike the β cell, glucagon secretion is stimulated at low glucose levels *(left panel)* and inhibited *(right panel)* by hyperglycemia. Potassium (K^+) channels are under strong tonic inhibition (99%) at low glucose levels, so that the membrane is depolarized sufficiently to elicit electrical activity, which consists of large-amplitude action potentials. Electrical activity is associated with activation of voltage-gated sodium (Na^+) channels and voltage-gated calcium (Ca^{2+}) channels, and Ca^{2+} influx through the latter triggers glucagon secretion. Increasing glucose levels to 6 mM closes K^+ channels completely, further depolarizing the membrane. (Modified from Ashcroft FM, Rorsman P. K(ATP) channels and islet hormone secretion: new insights and controversies. *Nat Rev Endocrinol.* 2013;9:660–669.)

hypoglycemia. Other substances that stimulate glucagon release include amino acids, epinephrine, and secretin.[10]

KEY POINTS

- Key inhibitory substances for insulin release are mediated mechanistically through negative regulatory G proteins that diminish glucose-induced insulin secretion. These include somatostatin, epinephrine, and prostaglandin E.

Glucagon is stored in granules prior to exocytosis and the secretory machinery is similar to that found in β cells. However, exocytosis is slightly faster than in β cells because of the higher number of granules per cell in the readily releasable pool. The rate of granule refilling after depletion of this pool is also higher in α cells, perhaps due to larger Ca^{2+} currents in relatively smaller cells.[9] Glucagon secretion exhibits a somewhat reciprocal relation to insulin secretion and has been characterized as a counterregulatory hormone protecting

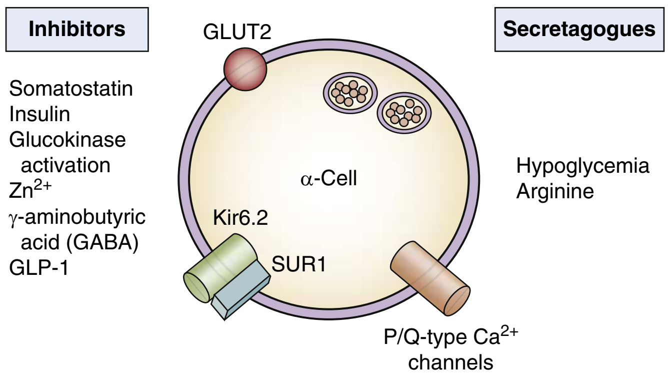

Fig. 29.10 Regulation of glucagon secretion.

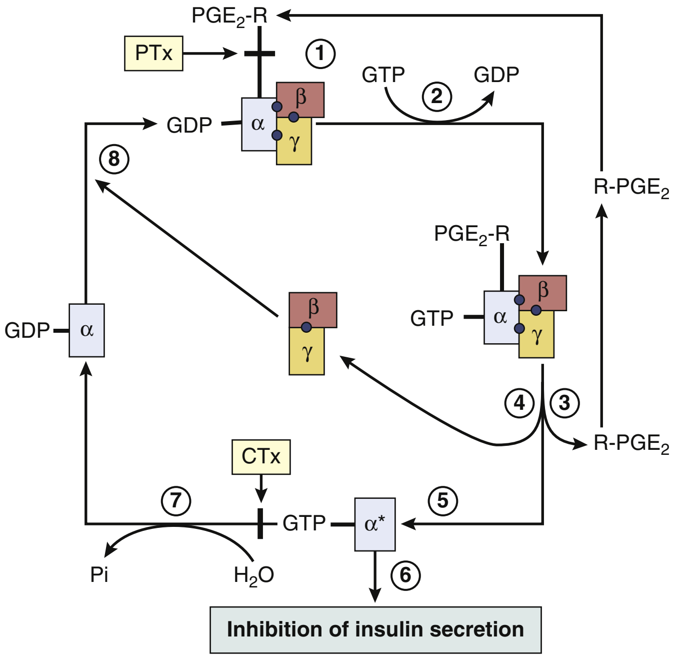

Fig. 29.11 Insulin Secretion is Modulated by G Proteins Within the β Cell. After formation of hormone–receptor complex, this associates with guanosine diphosphate (GDP)-binding G protein (comprised of α-, β-, and γ-subunits). This union promotes exchange of guanosine triphosphate (GTP) for GDP on the α-subunit (step 2). This forms an unstable complex that quickly dissociates into free HR complex (step 3), free β-γ-subunits (step 4), and activated α-subunit binding GTP (step 5). This activated species modulates islet effector systems, e.g., adenylylcyclase, ion channels, phospholipases, and distal sites in exocytosis (step 6). Activated species are inactivated by intrinsic GTPase activity of the α-subunit, which hydrolyzes bound GTP to GDP (step 7) and allows reassociation of α-GDP with the β-γ-subunit (step 8). This completes the cycle and returns G protein to its quiescent state. (Modified from Robertson RP, Seaquist ER, Walseth TF. G proteins and modulation of insulin secretion. *Diabetes.* 1991;40:1–6.)

against hypoglycemia. It is stimulated by low systemic glucose concentrations, enters the islet's periportal circulation, and travels to the liver via the portal vein, where it acutely mobilizes hepatic glycogen (glycogenolysis) to restore normoglycemia. In the presence of hyperglycemia, glucagon secretion is suppressed. However, beyond counteracting insulin-induced hypoglycemia, glucagon is also secreted tonically in the fasting state and consequently plays an important role in metabolic regulation during both the fasting and postprandial state.

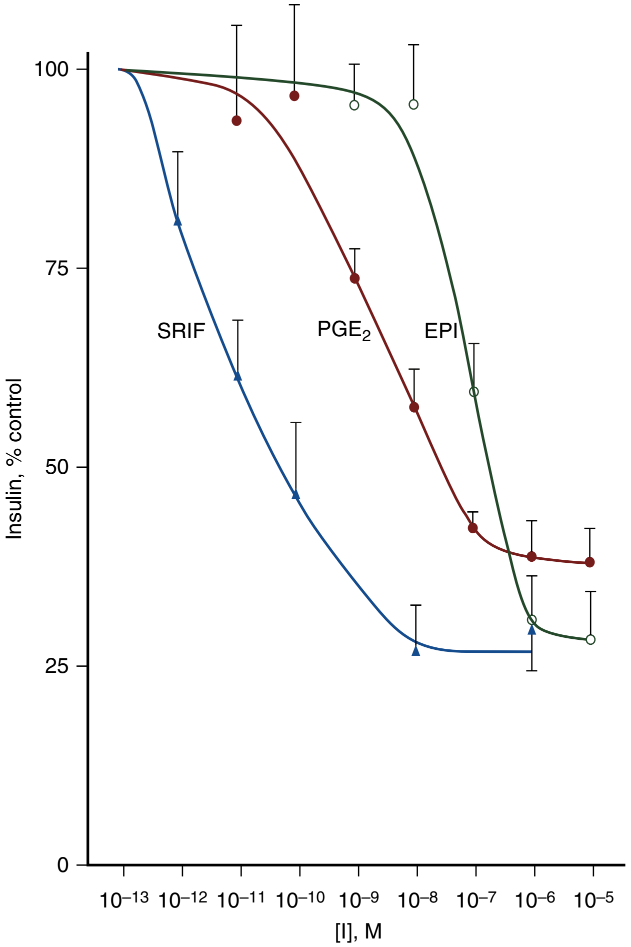

Fig. 29.12 Inhibition of insulin secretion during static 60-min incubations with 11.1 mM glucose (KRP buffer, pH 7.4) by increasing concentrations of somatostatin (SRIF), PGE2, and epinephrine (EPI) from four, five, and six separate experiments, respectively, performed in triplicate. PGE2 (IC^ 1 × 10”’ M) was more potent than epinephrine but less so than somatostatin. (Modified from Robertson RP, Tsai P, Little SA. Receptor-mediated adenylate cyclase-coupled mechanism for PGE2 inhibition of insulin secretion in HIT cells. *Diabetes.* 1987;36:1047–1053.)

KEY POINTS

- The secretion and action of insulin and glucagon in the regulation of glucose concentrations is reciprocal. The most important stimulator of glucagon secretion is hypoglycemia. At low glucose concentrations, β cells are hyperpolarized because of their open adenosine triphosphate (ATP)-sensitive potassium (K^+) channels. In contrast, α cells have a relatively elevated ATP/adenosine diphosphate ratio resulting in closure of most, but not all, ATP-sensitive K^+ channels, leading to depolarization and subsequent glucagon exocytosis. Secreted glucagon travels directly to the liver to stimulate glycogenolysis for release of glucose into the systemic circulation to correct hypoglycemia. The presence of hyperglycemia results in a further ATP increase within α cells. This results in closure of all K^+ channels. Key negative modulators of α cell function are insulin, glucose, and somatostatin.

Glucagon Signaling. Glucagon signals through a G protein–coupled receptor with seven transmembrane helices.[63] Hormone-receptor binding activates $G_{\alpha s}$-coupled proteins which increases cyclic adenosine monophosphate (cAMP) and activates protein kinase A (PKA) and cAMP response element–binding (CREB) protein. PKA activates phosphorylase kinase which, in turn, activates phosphorylase, resulting in mobilization of glycogen to glucose-1-phosphate while inhibiting glycogen synthase. Other actions of PKA impair glycolysis and increase gluconeogenesis. CREB directly induces transcription of glucose-6-phosphatase and phosphoenolpyruvate carboxykinase, which increases gluconeogenesis.[64]

The initial response to glucagon (increased release of glucose into the bloodstream from the liver) is the result of glycogenolysis rather than gluconeogenesis, because the latter requires gene transcription. The effects on glycogenolysis require phosphorylation, which can occur in minutes. Gluconeogenesis is substrate-driven, which requires activation of other mechanisms such as those mediated by cortisol or epinephrine.[65,66] Glucagon is most effective at increasing endogenous glucose production acutely. In situations where hepatic glycogen is depleted, as for example at the end of a 72-hour fast, no glucose response to glucagon is expected.[67]

Glucagon stimulates hepatic amino acid metabolism but does not directly promote amino acid release from skeletal muscle. To date there is no evidence of glucagon receptors on skeletal muscle in humans.[64] The role of glucagon in lipid metabolism is unclear.[64] Human adipocytes do not appear to express the glucagon receptor. It is possible that, by binding its hepatic receptor and activating CREB, it sets in chain a train of events that result in increased fatty acid catabolism. PKA activation also triggers a cascade of metabolic changes that produce increasing β-oxidation of free fatty acids rather than reesterification to triglycerides.[68]

Glucagon is an insulin secretagogue[45,69] in the concentrations found within the islet[70] during α cell dysfunction, as occurs in type 2 diabetes[71,72] and in prediabetes.[73,74] In these conditions, glucagon signals through the GLP-1 receptor present on β cells,[75] but its net contribution to physiologic insulin secretion is unknown.

Intrinsic Mechanisms Regulating α Cell Secretion. There are significant similarities between β cells and α cells with regards to their secretory apparatus. Glucagon secretory granule exocytosis is triggered by an influx of Ca^{2+} through voltage-dependent Ca^{2+} channels. An increase in extracellular glucose will lead to a decrease in intracellular Ca^{2+}. While α cells also express ATP-sensitive K^+ channels, voltage-dependent K^+ channels, and voltage-dependent Ca^{2+} channels, the isoforms of the latter group differ so that there is a greater contribution of P/Q channels in α cells compared with β cells.[76] Tetrodotoxin inhibits glucagon release, implying that voltage-dependent Na^+ channels also play a role in glucagon secretion.[10]

At low glucose concentrations, β cells are hyperpolarized because of their open ATP-sensitive K^+ channels (Fig. 29.6). In contrast, α cells have a relatively elevated ATP/ADP ratio, resulting in closure of most, but not all, ATP-sensitive K^+ channels, leading to depolarization and subsequent glucagon exocytosis (Fig. 29.11). The presence of hyperglycemia results in a further ATP increase within α cells. This results in closure of all K^+ channels. Taken together, these findings imply that small changes in K^+ channel conductance could regulate the glucagon secretory response to changing glucose concentrations.[9] This is supported by the observation that mice lacking functional K^+ channels exhibit impaired glucagon secretion during hypoglycemia.[77]

AMP-activated protein kinase (AMPK) may act as the sensing mechanism for the metabolic state that drives glucagon secretion. Hyperglycemia, which is associated with inhibition of glucagon secretion, inhibits AMPK activity. In addition, direct activation of AMPK stimulates glucagon secretion.[78]

Extrinsic Mechanisms Regulating α-Cell Secretion. Glucokinase, an enzyme that is expressed in α cells, may play a role in glucose-mediated regulation of glucagon secretion.[79] In addition to direct cellular responses to changes in glucose concentrations, factors extrinsic to the α cell also regulate glucagon secretion. Insulin reduces K^+ channel sensitivity to ATP, thereby restraining glucagon secretion. Studies examining the pulsatile secretion of insulin have suggested that, at least in healthy individuals, glucagon pulses are antiphasic to insulin pulses.[80] Type 2 diabetes is clearly a bihormonal disease characterized by delayed and decreased insulin secretion coupled with impaired postprandial suppression of glucagon.[81] The latter, a manifestation of α cell dysfunction, was thought to occur at a relatively late stage in the evolution of diabetes, perhaps because of disrupted insulin secretion. However, cross-sectional studies in people with prediabetes have suggested that defects in α cell secretion do not correlate with indices of insulin secretion. Indeed, impaired insulin signaling is a better marker of abnormal α cell regulation.[73,82] This may suggest that, beyond a minimum threshold of insulin secretion, it is the efficacy of insulin signaling that contributes to individual variation in glucagon secretion.[83] In addition, the association of genetic variants that predispose to type 2 diabetes with impaired glucagon suppression imply that these defects occur early in the evolution of diabetes.[84,85]

The β cell also secretes other inhibitors of glucagon secretion including zinc and γ-aminobutyric acid. Delta cell–secreted somatostatin is likely to inhibit glucagon secretion by the α cell. This assumes greater importance in insulin-deficient states. It has been demonstrated that antagonism of the somatostatin receptor increases α cell responses to arginine. Somatostatin receptor antagonists do not demonstrate significant effects on the response of glucagon to insulin-induced hypoglycemia in nondiabetic rodents. This is not the case in diabetic animals, where somatostatin receptor antagonists restore the glucagon responses to hypoglycemia.[76]

KEY POINTS

- Glucagon secretion is regulated by electrophysiological mechanisms intrinsic to the α cell. In addition, glucokinase expression in the α cell confers direct glucose sensing. The β cell also regulates glucagon secretion via paracrine effects of insulin and other inhibitors of glucagon secretion, including zinc and γ-aminobutyric acid. The delta cell, through the secretion of somatostatin, also inhibits glucagon secretion by the α cell.

Measurement of α-Cell Function *In Vivo*. The peptide sequence of glucagon overlaps considerably with that of other proglucagon-derived peptides. Many commercially available immunoassays are subject to significant crossreactivity with peptides such as oxyntomodulin and glicentin and may be insufficiently sensitive to adequately measure glucagon suppression by glucose. This issue may be a particular problem in patients with end-stage renal disease, where crossreacting glucagon fragments accumulate.[86,87] Currently, there are no specific tests of α cell function, and usually glucagon is measured as part of standardized challenges to measure β cell function.[88] A notable exception to this is glucagon-induced β cell secretion, where glucagon is used as a secretagogue. Of note, arginine-stimulation testing, which produces β cell stimulation similar to that produced by glucagon (with a lower incidence of nausea), potently stimulates glucagon secretion.[45] Postchallenge suppression of glucagon depends to a great extent on the nature of the caloric challenge, so that protein-containing meals can stimulate rather than suppress glucagon secretion.[65]

Glucagon-Like Peptide-1 Secretion and Signaling

As discussed previously, posttranslational processing of proglucagon in enteroendocrine cells yields a highly conserved peptide hormone, GLP-1.[89,90] GLP-1 signals through its cognate receptor, which shares its architecture with the glucagon receptor. Although GLP-1–based therapy is now used to treat type 2 diabetes and obesity,[91] important questions about its physiological role remain.[92] It has a $t_{1/2}$ of approximately 1 minute in the circulation due to rapid degradation by a ubiquitous peptidase, di-peptidyl peptidase-4.[93] A significant proportion of endogenous GLP-1 is degraded close to the site of production.[94] Competitive antagonism of the GLP-1 receptor with exendin-9,39 has little effect on postprandial insulin secretion, unless postprandial GLP-1 concentrations are markedly elevated.[31] These conditions are typically only fulfilled after Roux-en-Y gastric bypass[95] and, to a lesser extent, sleeve gastrectomy.[96] On the other hand, when infused at pharmacological concentrations, GLP-1 stimulates insulin secretion and suppresses glucagon secretion in a glucose-dependent manner.[97] These effects are accompanied by delayed gastric emptying of solids and an increase in gastric accommodation with accompanying changes in compliance (increased) and wall tension (decreased).[98,99] Many of these gastrointestinal effects are mediated through vagal signaling[99] but are subject to tachyphylaxis even after relatively brief periods of GLP-1 receptor agonism.[100] This is also observed with GLP-1 analogs used clinically to treat type 2 diabetes and obesity.[101]

KEY POINTS

- Glucagon-like peptide-1 (GLP-1) also arises from the posttranslational processing of proglucagon by prohormone convertase-1/3. Endogenous GLP-1 has a short half-life in the circulation because of the ubiquity of di-peptidyl peptidase-4, which degrades GLP-1 to an inactive form. Although debate as to the physiologic role of GLP-1 continues, in pharmacologic concentrations it is a powerful insulin secretagogue.

Other Proglucagon-Derived Peptides and Their Potential Role(s).

The oxyntomodulin sequence consists of glucagon with an additional eight amino acids at its C-terminus. It binds to both the glucagon and GLP-1 receptors with low affinity. It has elicited interest because at pharmacologic concentrations in rodents and humans it decreases caloric intake and increases energy expenditure.[102] Substitution of a single amino acid that prevents binding to the glucagon receptor abolishes most of its effects on weight, although there is further decrease in efficacy in GLP-1 receptor knockout mice.[103] These observations have underpinned the impetus to develop GLP-1 and glucagon receptor coagonists for the treatment of type 2 diabetes and obesity.

KEY POINTS

- Diabetes is a metabolic disease of persistent hyperglycemia owing to various mechanisms that cause deficiency of insulin and/or insulin action in various target tissues. Understanding the mechanisms that dysregulate insulin action is important because type 2 diabetes mellitus is associated with chronic life-threatening complications, including nonalcoholic fatty liver disease, nonalcoholic steatohepatitis, cardiovascular disease, kidney disease, and age-related neurodegeneration.

INTRODUCTION

Insulin and insulin-like growth factor signaling (IIS) integrates metazoan metabolism, growth reproduction, and lifespan with environmental signals.[1] Lower animals have a wide array of insulin-like peptides—thirty-eight in *Caenorhabditis elegans* and seven in fruit flies—that bind to a single insulin-like receptor tyrosine kinase.[2] The human genome encodes a smaller family of structurally related insulin-like peptides—including insulin itself, insulin-like growth factor (IGF) 1, and IGF2—which activate five similar receptor tyrosine kinases assembled from two genes. This chapter focuses mainly upon the insulin branch of mammalian IIS and its heterologous regulatory mechanisms.

Circulating glucose enters pancreatic islet β cells, where it promotes insulin gene expression and insulin secretion.[3] By contrast, endocrine IGF1 is secreted largely from hepatocytes during stimulation by nutrients, insulin, and growth hormone; however, IGF1 and IGF2 are also produced locally in many tissues and cells, including the central nervous system and various tumors.[4] IGF1 and IGF2 coordinate with insulin to regulate nutrient homeostasis, insulin sensitivity, pancreatic β cell function, and cell growth and survival.[4,5] Dysregulated insulin signaling is associated mainly with the “metabolic syndrome” and type 2 diabetes mellitus (T2DM), whereas dysregulated IGF1 and IGF2 signaling can promote cancer by inhibiting apoptosis and stimulating cell proliferation.[6]

Diabetes is a metabolic disease of persistent hyperglycemia owing to various mechanisms which cause deficiency of insulin and/or insulin action—including impaired glucose sensing or insulin secretion by pancreatic β cells (maturity onset diabetes of youth [MODY]); autoimmune-mediated β cell destruction (type 1 diabetes mellitus [T1DM]); or insufficient β cell insulin secretory capacity to compensate for peripheral insulin resistance (T2DM).[7] MODY is caused by mutations in at least 14 genes associated with β cell function—especially hepatocyte nuclear factor-4α (MODY1), glucokinase (GCK, MODY2), and hepatocyte nuclear factor-1α (MODY3).[8] Circulating autoantibodies against a variety of islet antigens, including insulin itself, are the hallmarks of T1DM.[9]

T2DM is the most prevalent form of diabetes that usually manifests at middle age, but can also develop in obese children and adolescents.[10] Physiologic stress owing to chronic excess nutrients and systemic inflammation impairs insulin action to promote T2DM.[11] The microbiome may also affect the onset and progression of obesity and T2DM owing to the production of metabolites that act as hormones, neurotransmitters, and inflammatory cytokines that can enter the circulation.[12,13] Genetic variations can attenuate or exacerbate the progression of metabolic disease and T2DM by directly or indirectly modulating the response to insulin.[14] Which genetic variations might converge upon a short list of novel "druggable" targets to prevent T2DM remains to be established.[15,16]

Understanding insulin signaling is important because T2DM is associated with chronic life-threatening complications—including nonalcoholic fatty liver disease (NAFLD) and nonalcoholic steatohepatitis (NASH)[17], cardiovascular and kidney disease[18], and age-related neurodegeneration.[19] Drugs that reduce metabolic stress can have beneficial effects, including metformin[20] and sodium-glucose cotransporter 2 inhibitors.[21] Calorie restriction or intermittent fasting can promote nutrient homeostasis and reduce the demand for increased insulin signaling to promote health and longevity across all metazoans—including people.[22]

KEY POINTS

- The discovery of insulin 100 years ago and its application to the treatment of human disease marked a major turning point in the history of medicine. Our understanding of how insulin works has progressed over the last 50 years, starting with the identification of the insulin receptor and its tyrosine kinase activity. Understanding the insulin and insulin-like growth factor signaling systems as important integrators of metabolism, growth, and lifespan has expanded our understanding of insulin resistant states and diabetes.

INSULIN

Insulin was purified 100 years ago and used to treat T1DM. Some 50 years later the structure of insulin was solved.[23] During the past 50 years, the insulin receptor (InsR) has been identified, and its signaling mechanisms have been investigated.[1,24-26]

Insulin is synthesized in pancreatic β cells as a single polypeptide (proinsulin) that is processed by prohormone convertase-1/3 to excise the "C-peptide" and generate the bioactive disulfide-linked A- and B-chains composed of three α-helices (Fig. 30.1A).[1] Human IGF1 and IGF2 display high sequence similarity with the A- and B-chains of insulin while retaining the C-peptide (Fig. 30.1B).[27] Insulin dimerizes through a β-sheet between the two C-terminal portions of the insulin B-chain, including residues Phe^{B24}, Phe^{B25}, and Tyr^{B26} (see Fig. 30.1A). Three insulin dimers form a hexamer in the presence of zinc; however, IGFs do not aggregate because the connecting peptide blocks the dimerization surface.[25]

Insulin possesses two asymmetric receptor binding surfaces called "S1" (the classical site) and "S2" (the novel site) (see Fig. 30.1A).[28] Natural mutations of insulin, together with alanine-scanning mutagenesis and structural refinements, show that the high-affinity receptor binding site (S1, $K_d = 6$ nM) is composed of residues from the A- and B-chains (see Fig. 30.1A).[29,30] Phe^{B24}, Phe^{B25}, and Tyr^{B26} of the dimerization surface undergo a conformational change to facilitate high-affinity insulin binding (Fig. 30.1C).[1,31] A second receptor binding site (S2) is on the opposite side of insulin (see Fig. 30.1A).[29] Most of these contacts have been validated by cryo–electron microscopy (EM) to interact with specific regions in the α-subunit of the InsR.[32]

KEY POINTS

- The insulin receptor (InsR) precursor is encoded by a 150-kb gene composed of 22 exons on human chromosome 19p13.3-p13.2. The *INSR* gene encodes the extracellular domain that binds insulin and the intracellular tyrosine kinase that is activated during insulin binding. Feedback and heterologous signaling cascades modulate the activity of the InsR to integrate metabolism throughout the body.

Introduction

Most receptor tyrosine kinases (RTKs) exist as monomers that span the plasma membrane once and dimerize during ligand binding to bring two intracellular kinase domains into proximity for tyrosine transphosphorylation, which initiates downstream signaling (Fig. 30.2).[26] Bivalent or dimerized ligands are common strategies to homodimerize receptors through their extracellular immunoglobulin-like domains—including receptors for platelet-derived growth factor, vascular endothelial growth factor (VEGF), fibroblast growth factor, nerve growth factor, and others (see Fig. 30.2). By comparison, epidermal growth factor binding exposes a dimerization surface on the epidermal growth factor receptor (EGFR) that facilitates transphosphorylation to activate the dimers.[26] Insulin and IGFs are bivalent ligands that activate the preexisting catalytically inactive receptor dimer by inducing a receptor-wide conformational change that brings the catalytic domains into close proximity (see Fig. 30.2).[24,33]

Structure and Function of the Extracellular Domain of the Insulin Receptor

The InsR proreceptor is encoded by a 150-kb gene composed of 22 exons on human chromosome 19p13.3-p13.2, which encodes the extracellular domain (ECD) and the intracellular RTK (Fig. 30.3A). During synthesis, the proreceptor enters the endoplasmic reticulum, where it is glycosylated and stabilized by disulfide bonds, and then moves into the Golgi, where furin cleaves it at the Arg-Lys-Arg-Arg motif to generate the αβ·αβ dimer (Fig. 30.3A and B).[25,34] The ECD is composed of the entire α-subunit and an N-terminal portion of the β-subunit. The α-subunit begins with two N-terminal leucine-rich repeats (L1, amino acids [aa] 1–155; L2, aa 315–470) flanking a cysteine-rich (aa 195–310) region containing eight modular cysteine-linked repeats (see Fig. 30.3B). These modules are followed by three fibronectin-III motifs—including $\text{Fn}_{\text{iii}}1$ (aa 473–591) and $\text{Fn}_{\text{iii}}3$ (aa 808–904) flanking $\text{Fn}_{\text{iii}}2$ (aa597–717)—that are interrupted by a 120-aa insert domain containing the furin cleavage site (aa 636–690) (see Fig. 30.3A and B).

The disulfide-linked α-subunits and extracellular portion of the β-subunits fold into an inverted V configuration, with the apex formed by the L2 and $\text{Fn}_{\text{iii}}1$ domains (Fig. 30.3C).[35] Site-directed mutagenesis and photo-affinity labeling experiments with wild-type and mutant InsR originally predicted the location of two insulin-binding sites in the α-subunit. The high-affinity site-1 is composed of L1 from one α-subunit and CTa' (aa 693–710) from the other (Fig. 30.3D).[36,37] Cryo-EM resolves several points of contact of insulin with $\text{Fn}_{\text{IiI}}1$ and CTa, which increase binding affinity. When the InsR is saturated at high insulin concentrations, cryo-EM reveals the location of a distinct low-affinity binding site-2 near the $\text{Fn}_{\text{iii}}1$–$\text{Fn}_{\text{iii}}2$ interface (see Fig. 30.3D).[26,32,35,38] Insulin binding to site-1 and site-2 can stabilize the ECD in the T conformation, promoting convergence of the adjacent membrane-proximal $\text{Fn}_{\text{iii}}3$ domains toward each other, which transmits a conformational change through the hydrophobic transmembrane domain (TMD) to mediate tyrosine transphosphorylation of the RTK.[39]

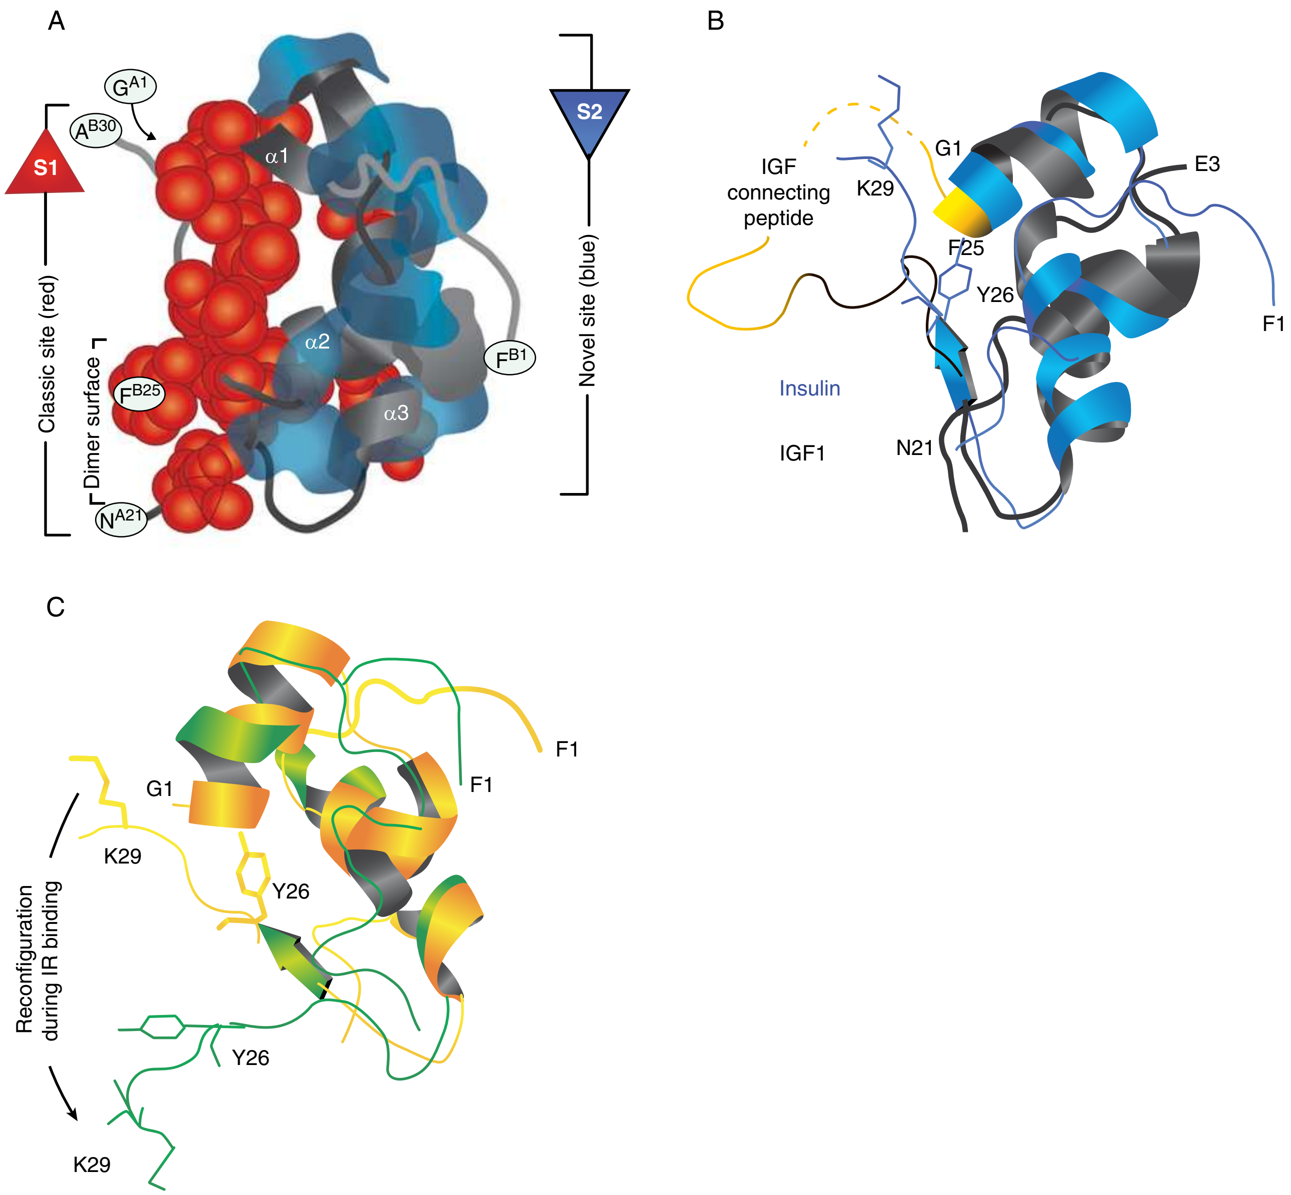

Fig. 30.1 Structural features of insulin and insulin-like growth factor 1 (IGF1). A, Pig insulin structure (pdb id 4 ins) showing the position of amino acids that compose the two binding surfaces (S1 and S2) that interact with the L1·CR·CT and $Fn_{iii}1 \cdot Fn_{iii}2$ regions of the insulin receptor, respectively (see Fig. 30.3). The insulin A- chain is shown in red, the B-chain is shown in blue, and the amino- and carboxyl-terminal residues of each chain are labeled, together with Phe25 of the B chain. B, Structural alignment of human insulin (in blue, pdb id 4ins) and insulin-like growth factor 1 (in black, pdb id 1imx), highlighting (in yellow) the position of the connecting peptide in IGF1 that is absent in the mature insulin polypeptide. C, Structural comparison of unbound insulin (in yellow, pdb id 4ins) versus that of insulin bound to the high affinity site on the insulin receptor (in green, pdb id 6sof). Cartoons were created in PyMOL (The PyMOL Molecular Graphics System, Version 2.0 Schrödinger, LLC.)

Exon 11 of the *INSR* gene is alternatively spliced depending upon the tissue and developmental stage to produce two InsR isoforms—including IRA that omits exon 11 and IRB that includes exon 11, adding 12 aa to the CTα (C-terminus of the α-subunit) (Fig. 30.3F).[28] Insulin binds with high affinity ($K_d < 0.5$ nM) to the homodimeric IRB ($\alpha\beta^{IR} \cdot \alpha\beta^{IR}$), which predominates in adult liver, muscle, and adipose tissues. IRA binds insulin with slightly lower affinity, but unlike IRB also binds IGF1 and IGF2 in the physiologic range (see Fig. 30.3F).[4,40] The homologous IGF1R homodimer ($\alpha\beta^{IGF1R} \cdot \alpha\beta^{IGF1R}$) is assembled without alternative splicing from its 19-exon gene located on human chromosome 15. IGF1R binds IGF1 and IGF2 with high affinity but binds insulin weakly (Fig. 30.3F). Binding affinity of the hybrid receptors ($\alpha\beta^{IR} \cdot \alpha\beta^{IGF1R}$) resemble IGF1R, which bind insulin with low affinity (see Fig. 30.3F).[41] Because the InsR occurs in two isoforms, a total of five receptors are generated from the two receptor genes (see Fig. 30.3F). Under ordinary conditions, insulin never activates the IGF1R tyrosine kinase, whereas IGF1 and IGF2 can activate the InsR tyrosine kinase while dimerized with the IGF1R.[42] IRA mediates the effects of

Fig. 30.3 **Insulin receptor and insulin-like growth factor (IGF) 1 receptor hybrids.** A, Diagram of the insulin receptor (InsR) precursor showing the position of important modules in the α- and β-subunits—including leucine-rich regions (L1 and L2), a cysteine-rich region (CR); fibronectin iii domains (Fn$_{iii}$1, Fn$_{iii}$2a, Fn$_{iii}$2b, Fn$_{iii}$3); the insert domains IDa and IDb flanking the Arg-Lys-Arg-Arg furin cleavage site; the alternative IRA/IRB splice site that generates the short CTα^{IRA} or long CTβ^{IRB}; a transmembrane region (TM); the IRS binding motif (NPEpY); the activation loop autophosphorylation sites; and C-terminal tyrosine phosphorylation sites (CT). B, Diagram of the mature insulin receptor composed of two extracellular α-subunits and two transmembrane β-subunits. Contiguous modules of the two α-subunits are indicated with the relative location of disulfide bonds (S-S) between cysteine residues of the α and β subunits. Two regions within the α-subunit contribute to insulin binding—including L1·CR and the CTα that binds S1 of insulin, and the junction between Fn$_{iii}$1 and Fn$_{iii}$2 that binds S2 of insulin. The β-subunit contains the tyrosine kinase catalytic domain with an ATP binding site (Lys$_{1030}$) and several tyrosine phosphorylation sites. C, Cartoon of the inactive conformation of the extracellular domain (ECD) of the InsR (pdb id 6pxv). One ECD is shown in color, with the various modules of the a-subunit traced with a black line; the β-subunit is shown in dark grey; the adjacent ECD is shown in light grey. D, Cartoon of the active conformation of the ECD of the InsR (pdb id 6SOF).[39] The conformational change of the insulin-occupied ECD is illustrated by the black line tracing the relative location of various modules of the α-subunit, which brings the Fn$_{iii}$3 domain together with the adjacent Fn$_{iii}$3′ domain to facilitate transphosphorylation of the intracellular RTK. E, The transmembrane domain linking the Fn$_{iii}$3 domain of the ECD to the juxtamembrane region of the receptor tyrosine kinase (pdb id 2MFR). F, The insulin and IGF family of receptors. The insulin/IGF family consists of three peptide hormones—including insulin, IGF1, and IGF2—which bind as indicated to five distinct homo- or heterodimeric receptor isoforms—including IRA, IRB, IGF1R, and two hybrid receptors, IRA·IGF1R and IRB·IGF1R. The approximate binding affinities (K$_d$, nM) are shown in the figure.

IGF2 during embryogenesis and fetal development and in the adult brain.[4]

Regulation of the Insulin Receptor Tyrosine Kinase

Hard-won biochemical results obtained using [^{32}P]-labeled cells and proteins revealed the tyrosine kinase activity of the InsR[43]; however, until the InsR cDNA was isolated and sequenced,[44,45] other mechanisms for signal transduction were proposed—and some still persist.[46,47] Regardless, the discovery that rare cases of severe insulin resistance in humans are associated with *INSR* mutations that inactivate the tyrosine kinase—without altering insulin binding—supports the central hypothesis that tyrosyl phosphorylation initiates the intracellular signaling cascade.[43,48]

The intracellular portion of the InsR β-subunit begins with a 30-residue juxtamembrane domain (JMD) between the TMD and the tyrosine kinase domain that terminates with the 70-residue C-terminus (see Fig. 30.3A). Each intracellular region contains tyrosyl phosphorylation sites (numbered as in IRB): Tyr^{965} and Tyr^{972} in the JMD; Tyr^{1158}, Tyr^{1162}, and Tyr^{1163} in the activation loop (A-loop) of the kinase domain; and Tyr^{1328} and Tyr^{1334} in the C-terminus (see Fig. 30.3B).[49,50] Before insulin binds, the adjacent kinase domains of the $(\alpha\beta)_2$ dimer are widely separated to suppress transphosphorylation.[51] Conformational changes in the ECD during insulin binding reduce the distance between the TMD to facilitate transphosphorylation (compare Fig. 30.3C and D). In addition to kinase proximity, other mechanisms inhibit InsR kinase activity: (1) the unphosphorylated Tyr^{1162}—the second of the three A-loop tyrosine residues—blocks access of peptide substrates to the active site; (2) Asp^{1161} preceding Tyr^{1162} stabilizes the closed A-loop to inhibit unstimulated transphosphorylation[52]; (3) the N-terminal end of the A-loop (Asp-Phe-Gly motif) competes to elevate the $\mathrm{K_m}$ for adenosine triphosphate (ATP).[24] Early studies suggest that multisite transphosphorylation in the A-loop generates the insulin signal.[49] Intramolecular transphosphorylation begins at Tyr^{1158} and progresses to Tyr^{1162} and slowly to Tyr^{1163} until tris-phosphorylation stabilizes the open A-loop to fully activate the kinase (Fig. 30.4A–C).[53,54] This model of kinase regulation is confirmed by an Asp to Ala substitution at residue 1161 that shifts the A-loop toward the open configuration.[52] Substitution of Tyr^{1162} with Phe also increases basal transphosphorylation, consistent with its role to stabilize the closed conformation or block ATP and protein substrate entry into the active site (see Fig. 30.4C).[55,56]

The Insulin Receptor–Related Receptor

A third gene encodes the insulin receptor–related receptor (IRR), which has 50% identity (65% similarity) to the receptors for insulin and IGF1.[57] High-affinity peptide ligands are unknown for the IRR because the structure of the extracellular domain is rather different than that of the InsR.[58] The IRR is activated by exposure to alkaline environments, which generates insulin-like signaling in several tissues—including kidney, pancreas, stomach, ovary, and nerves.[58] The structure of the homologous IRR is different, as it assumes a unique conformation owing to a shorter distance between the fibronectin domains within the ECD.[58] Importantly, pH changes fail to induce conformational changes in the ECD, suggesting that the IRR may sense alkaline conditions inside the cell by changes in the JMD of the β-subunit. The IRR, together with the InsR and IGF1R, promotes male sexual development in mice.[57]

THE INSULIN SIGNALING CASCADE

KEY POINTS

- The insulin receptor (InsR) signal is transmitted into the cell through tyrosine phosphorylation of a family of insulin receptor substrates called IRS1, IRS2, IRS3 (rodents), and IRS4 that bind to various signaling proteins to control glucose uptake and metabolism and protein and lipid synthesis and degradation. The IRS complex can dissociate from the InsR to carry the signaling complex into the cell.

Introduction

Following discovery of the InsR tyrosine kinase, many groups searched for cellular proteins that may mediate downstream signals.[33,59] The first evidence for a substrate of any RTK came from antiphosphotyrosine antibody immunoprecipitates that revealed a 185-kDa phosphoprotein (pp185) in insulin-stimulated hepatoma cells.[60] Purification and molecular cloning of pp185 revealed the first member of a family of signaling scaffolds engaged by RTKs and the first insulin receptor substrate, called IRS1.[61] Three homologous *IRS* genes are expressed in human tissues—including *IRS1*, *IRS2*, and *IRS4*—whereas rodents also express IRS3 in adipose tissue.[62] IRS1 and IRS2 are broadly expressed in mammalian tissues, whereas IRS4 is mainly restricted to the hypothalamus.[63,64] Work with transgenic mice reveals that systemic IIS is largely mediated through IRS1, IRS2, or both.

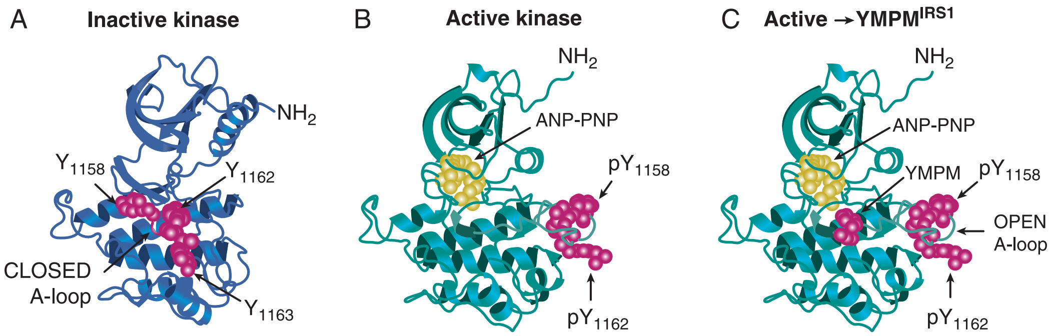

Fig. 30.4 **Structure and functional intracellular domains of the insulin receptor (InsR).** A, The inactive structure of the InsR kinase domain below the juxtamembrane domain is shown (pdb id 1IRK). The tyrosine residues of the A-loop are labeled and shown as red space-filling residues in the closed conformation. B, Following autophosphorylation of A-loop tyrosine residues (red space-filling), the A-loop moves out of the catalytic site to allow entry of adenosine triphosphate (yellow space-filling) to enter the active site (pdb id 1IR3). C, Peptide substrates such as YMXM-peptides of the IRS proteins enter the catalytic sites when the A-loop is open.

Insulin Receptor Tyrosine Protein Scaffolds

IRS proteins are composed of tandem, structurally similar, pleckstrin homology (PH) and phosphotyrosine binding (PTB) domains, followed by a long unstructured tail of tyrosine phosphorylation sites that coordinate downstream signals. IRS proteins also contain serine/threonine phosphorylation sites, which modulate IIS through feedback or heterologous mechanisms (Fig. 30.5). IRS proteins are strongly conserved in *Drosophila* to humans. Upon insulin stimulation, the IRS proteins are recruited to the JMD of the activated tyrosine kinase, where several tyrosine residues in the unstructured tail are phosphorylated and bind to the Src homology 2 (SH2) domains in various signaling proteins—especially the 85-kDa regulatory subunit (p85) of the phosphatidylinositol 3-kinase (PI3K) (Fig. 30.6). The binding between phosphorylated YMPM-motifs in IRS1 and both SH2 domains in PI3K was the first insulin signaling cascade to be reconstituted *in vivo* and *in vitro* (see Fig. 30.6).[65] Tyrosine phosphorylation of other sites in IRS1 or SHC (SHC adaptor protein 1) can recruit Grb2·SOS, which activates the mitogen-activated protein kinase cascade composed of RAS→MEK→ERK (Fig. 30.6).

Tyrosine phosphorylation of specific residues in IRS is accomplished through at least two mechanisms: (1) specific recruitment of the PTB domain of IRS to the phosphorylated NPEpY motif in the JMD of the InsR; and (2) recognition of specific phosphorylation motifs in the tail by the activated InsR catalytic domain. Based upon phosphopeptide mapping, tandem mass spectroscopy analysis, and phosphorylation of synthetic peptides, several motifs in IRS1 have been identified as optimal InsR substrates—including several YMXM-motifs and the YVNI-, YIDL-, and YASI-motifs.[66-68] There are other tyrosine phosphorylation motifs conserved in IRS1 and IRS2, but their functional specificity is poorly characterized (see Fig. 30.5). The phosphorylated motifs are recognized by the InsR catalytic domain as antiparallel β-strands relative to the C-terminal end of the open A-loop, positioning the site into two hydrophobic pockets on the activated kinase.[67]

The selective and regulated recruitment of IRS to the activated InsR and IGF1R adds an essential level of signaling specificity. The IRS proteins or SHC bind through their PTB domain to the NPEpY^{972} motif in the juxtamembrane region of InsR, which fills an L-shaped cleft on the PTB-domain[69,70]; however, the

Fig. 30.6 **A canonical insulin/insulin-like growth factor (IGF) signaling cascade.** Two main branches propagate insulin signals generated via tyrosine phosphorylation of the IRS proteins, which bind and activate the PI3K and GRB2·SOS cascades. The Grb2/SOS complex promotes GDP/GTP exchange on p21^{Ras}, which activates the RAS→RAF→MEK→ERK1/2 cascade. Activated ERK stimulates transcriptional activity by direct phosphorylation of ETS domain-containing protein (ELK1) and by indirect phosphorylation of cFOS through MAPK-activated protein kinase-1 (MAPKAPK1). MAPKAPK1 also phosphorylates other proteins including S6 (ribosomal protein S6), NFkB, PP1 and MYT1. The activation of PI3K by recruitment to IRS produces PI3,4P$_2$ and PI3,4,5P$_3$ (antagonized by the action of PTEN or SHIP2), which recruits PDK1 and AKT to the plasma membrane. AKT is activated upon phosphorylation at T308 by PDK1 and at S473 by mTORC2. mTORC1 is activated by Rheb^{GTP}, which accumulates upon inhibition of the GAP activity of the TSC1·TSC2 complex following AKT-mediated phosphorylation of TSC2. mTORC1-mediates phosphorylation of S6K and SREBP1, which promotes protein or lipid synthesis, respectively. AKT phosphorylates many cellular proteins inactivating PGC1α, p21^{kip}, GSK3β, BAD and AS160, and activating PDE3b, PCK1 and eNOS. AKT-mediated phosphorylation of FOXO1 causes their sequestration in the cytoplasm, which inhibits their influence upon transcriptional activity. Insulin stimulates protein synthesis by altering the intrinsic activity or binding properties of key translation initiation and elongation factors (eIFs and eEFs, respectively), as well as critical ribosomal proteins. Components of the translational machinery that are targets of insulin regulation include eIF2B, eIF4E, eEF1, eEF2, and the S6 ribosomal protein.[114]

NPEpY^{972}-motif is a low-affinity binding site for the PTB domain of IRS1 (Kd ~87 μM), owing to a destabilizing effect of E^{971} that is essential for autophosphorylation of Y^{972} by the InsR.[24,71] By comparison, the PTB domain of SHC binds to NPEpY^{972} with a much higher affinity (K_d ~4 μM) (see Fig. 30.6). Regardless, the structurally similar but functionally distinct PH domain immediately upstream of its PTB domain helps recruit IRS1 to the InsR (see Fig. 30.6).[72,73] The molecular specificity of the IRS PH domain remains to be established, as heterologous PH domains substituted from other proteins reduce InsR signaling.[74,75]

IRS2 uses an additional mechanism—the kinase regulatory-loop binding (KRLB) domain—to interact with the InsR (see Fig. 30.5).[76,77] Structural analysis reveals that Tyr^{621} of IRS2 inserts into the receptor ATP binding pocket, whereas Tyr^{628} aligns for transphosphorylation.[78] This interaction may promote IR→IRS2 signaling, because the KRLB interaction is apparently absent in the IGF1R.[78]

The IRS→PI3K→AKT Cascade

PI3K. The PI3K→AKT cascade begins when insulin stimulates tyrosyl phosphorylation of YMPM-motifs in IRS proteins, which directly bind and activate the class 1A PI3K (see Fig. 30.6).[79] The PI3K is composed of a catalytic and a regulatory subunit. The catalytic subunit—including the widely expressed p110α (PIK3CA) and p110β (PIK3CB), and the leukocyte-restricted p110δ (PIK3CD) and p110γ(PIK3CG)—is inhibited and stabilized upon association with an 85-kDa regulatory subunit. Several regulatory subunits include p85α (PIK3R1) and p85β (PIK3R2). Alternative splicing of PIK3R1 produces p55α or p50α, and PIK3R3 encodes p55γ, both of which lack some of the N-terminal regulatory features of p85 while retaining affinity toward the catalytic subunits.[80,81] All the regulatory subunits contain two SH2 domains that bind phosphorylated YXXM motifs, which disinhibit the catalytic domain to produce phosphatidylinositol 3,4,5-trisphosphate (PI(3,4,5)P3).[82-84] Inhibition of PI3K production by chemical or genetic means blocks almost all metabolic responses stimulated by insulin—including glucose influx, glycogen and lipid synthesis, and adipocyte differentiation—confirming that PI3K is a critical node coordinating insulin action.

Upon binding of p85 to phosphorylated YMPM motifs in IRS, the activated PI3K converts PI(3,4)P2 into PI(3,4,5)P3, which binds to the PH domains in various signaling proteins to recruit and activate them at the plasma membrane—including 3'-phosphoinosotide-dependent protein kinase-1 (PDK1), v-akt murine thymoma viral oncogene (AKT), and target of rapamycin complex 2 subunit MAPKAP1 (SIN1). AKT is activated by phosphorylation at Thr^{308} in the A-loop by the juxtaposed PDK1 (see Fig. 30.6). SIN1 is recruited to the plasma membrane by PI(3,4,5)P3, where it is phosphorylated at Thr^{86} by $\text{pT308}^{\text{AKT}}$. SIN1 complexes with mTORC2, which phosphorylates Akt at Ser473.[85] Bis-phosphorylated AKT can phosphorylate a wider array of substrates, including FOXO transcription factors (see Fig. 30.6). In adipocytes and muscle, SIN1 can recruit atypical protein kinase C to PI(3,4,5)P3, where it can be activated by PDK1 and promote insulin-stimulated glucose uptake.[81,86,87] Finally, SIN1 can be phosphorylated by ribosomal protein S6 kinase (S6K1), which creates a feedback mechanism to inhibit mTORC2.[85,88,89]

AKT. Mammalian AKT1, AKT2, and AKT3 phosphorylate more than 100 substrates that control cell survival, growth, proliferation, angiogenesis, metabolism, and migration (see Fig. 30.6). Although overlap exists, AKT1 mainly regulates development, growth, and survival, whereas AKT2 regulates metabolism through insulin-stimulated GLUT4 translocation and liver glucose and lipid metabolism.[90] Human subjects with a dominant negative mutation in AKT2 display features of T2DM.[91] AKT3 promotes neuronal development, and homologous glucocorticoid-regulated kinase 3 (Sgk3) synergizes with AKT2 in pancreatic β cells to stimulate proliferation and insulin release.[92,93]

mTORC1. Mechanistic target of rapamycin (mTOR) is a Ser/Thr kinase that belongs to the PI3K-related kinase family and forms two large functionally distinct protein complexes—mTORC1 and mTORC2—owing to the assembly of common and unique subunits.[94] Both complexes are controlled by insulin, IGF1, and other growth factors through the PI3K→AKT cascade; however, each complex is recruited to different compartments and responds distinctly to nutrients, stress, hypoxia/energy status, and other factors.[94] mTORC1 is targeted to the lysosome, where it is inhibited by the TSC1·TSC2 complex until AKT phosphorylates and inhibits TSC2 (tuberin)—a GTPase-activating protein (GAP)—which promotes GTP·Ras homolog enriched in brain (RHEB) accumulation (see Fig. 30.6). FK506 binding protein 8 (FKBP8) inhibits mTORC1 until RHEB·GTP promotes its dissociation from mTORC1.[95] Regulation by TSC1·TSC2→RHEB is also modulated by AKT-mediated phosphorylation of AKT substrate 1, which promotes its dissociation from RAPTOR to activate mTORC1.[92] RHEB resides on endomembranes, including lysosomes, where it can interact with mTORC1 only if enough amino acids are available (see Fig. 30.6).[96,97] The dependence upon amino acids ensures that the cellular environment is sufficient to support growth factor (insulin) action. Activated mTORC1 promotes many cellular anabolic processes needed for growth and proliferation—including the stimulation of glycolytic flux and mitochondrial function, protein and lipid synthesis, and the inhibition of autophagy and lysosomal biogenesis (see Fig. 30.6).[89] Thus, the IRS→PI3K→AKT→mTORC1 cascade controls many key cellular processes that balance cellular integrity, long-term growth, and survival.

mTORC2. In addition to fully activating AKT, mTORC2 plays a role in mRNA processing when it phosphorylates insulin-like growth factor 2 mRNA-binding protein 1, which promotes IGF2-leader 3'-mRNA translational initiation by internal ribosomal entry.[98] Thus, mTORC2 can promote growth by regulating IGF2 production, which can activate IRA in the mouse embryo. mTORC2 also regulates protein ubiquitination by phosphorylating F-box and WD repeat domain–containing 8 (FBW8), a Cullin 7 E3 ubiquitin ligase recognition subunit (see Fig. 30.6). The phosphorylation of FBW8 stabilizes and promotes ubiquitination of targeted substrates, including IRS1, which contributes to insulin resistance in certain tissues and cells (see Fig. 30.6).[99] Thus, mTORC2 signaling can modulate IIS through its direct effect upon AKT activity and its indirect control of IIS regulatory nodes.[98]

FOXO. Forkhead box O subfamily (FOXO) proteins—FOXO1, FOXO3a, FOXO4, and FOXO6—are integrative transcription factors that control target gene expression to coordinate many biological process, including metabolism, autophagy, apoptosis, reactive oxygen species detoxification, DNA repair, cell cycle, stem cell maintenance, and longevity.[100] FOXOs contain five highly conserved domains, including the N-terminal region with several AKT phosphorylation sites[101]; a highly conserved forkhead DNA binding domain (DBD); a nuclear localization signal located just downstream of the DBD; a nuclear export sequence; and a C-terminal transactivation domain.[102] Retention of FOXO in the nucleus promotes or suppresses expression of genes by binding to TTGTTTAC motifs.[103] FOXO nuclear localization is regulated by various posttranslational modifications, including acetylation, methylation, glycosylation, and ubiquitylation[104]; however, one of the most critical is phosphorylation by AKT or other kinases, including IκB kinase and SGK, which promotes nuclear exclusion.[101,103] Deacetylation of FOXO by silent mating type information regulation NAD-dependent deacetylase (SIRT1) can suppress transcriptional activity directly.[105]

FOXOs regulate metabolism by inducing genes that promote hepatic glucose production (HGP); insulin secretion in β cells and β cell growth and differentiation; and fat and muscle mass.[106-108] In mammalian liver, decreased circulating insulin during fasting promotes the nuclear localization of FOXO, where it interacts with peroxisome proliferator-activated receptor gamma coactivator 1-alpha (PGC1α) and cAMP response element-binding protein (CREB) complexed with CREB regulated transcription coactivator 2 (CRTC2) to increase the expression of glucose-6-phosphatase (G6PC) and phosphoenolpyruvate carboxykinase 1 (PCK1) for HGP.[109] FOXO also regulates hundreds of other hepatic genes directly or indirectly to coordinate glucose and lipid homeostasis and systemic insulin sensitivity. Severe and persistent starvation can trigger FOXO1-mediated hepatic insulin-like growth factor-binding protein 1 expression to reduce circulating IGF1 bioavailability and attenuate somatic growth.[110] In muscle, nuclear FOXO1 promotes autophagy that breaks down muscle protein for use by the liver to make glucose. Thus, reduced IIS in skeletal muscle can underlie the loss of muscle mass and glycemic control during chronic insulin resistance.[111]

Insulin-Regulated Proteostasis

Protein synthesis is one of the best understood mTORC1-regulated processes that is controlled, at least in part, through phosphorylation/

activation of S6K1/2 (the ribosomal protein S6 kinases) and phosphorylation/inhibition of eukaryotic translation initiation factor 4E binding protein 1 (4E-BP1) (see Fig. 30.6). Insulin mainly stimulates protein synthesis in liver, while it suppresses protein degradation and amino acid release by muscle; however, hepatic protein synthesis can occur during starvation owing to influx of amino acids from muscle. Muscle expresses receptors for insulin and IGF1, but deletion of the InsR reduces muscle size by 20%, while deletion of the IGF1R has no effect; however, deletion of both receptors is usually fatal, as it decreases muscle size by at least 60%.[112] The deletion of muscle IRS1 or IRS2 barely influences skeletal muscle mass; however, deletion of both reduces muscle mass by approximately 50%.[113] Thus, InsR is more important than IGF1R, and both IRS1 and IRS2 contribute to muscle proteostasis. In the absence of InsR and IGF1R, the compound deletion of FOXO1, FOXO3, and FOXO4 can prevent muscle loss.[112]

Insulin coordinates protein synthesis through various translation factors—including eIF2B (multisubunit guanine nucleotide exchange factor for translation initiation factor eIF2), eIF4E (mRNA cap-binding protein), eEF1 (eukaryotic elongation factor 1), eEF2 (eukaryotic elongation factor 2), and the S6 ribosomal protein[114,115] (see Fig. 30.6). During insulin stimulation, AKT—┤ GSK3β reduces phosphorylation of eIF2Bε, which promotes the formation of $eIF2^{GTP}$ that recruits $tRNAi^{Met}$ to the ribosome to promote translation initiation.[114,116] Translation initiation also involves eukaryotic initiation factor 4F (eIF4F) that directs ribosomes to the cap structure of mRNAs. Translation initiation is strongly inhibited by 4E-BP1, which directly interacts with eIF4E to block the eIF4F complex from repressing translation (see Fig. 30.6). mTORC1-mediated phosphorylation of 4E-BP1 dissociates the 4E-BP1·eIF4E complex to allow interaction between eIF4E and the eIF4G scaffold protein in the eIF4F complex (see Fig. 30.6).[117] MAP kinase-interacting serine/threonine-protein kinase 1, an insulin-stimulated kinase activated through the RAS→ERK cascade, also resides in the eIF4F complex, where it phosphorylates eIF4E (see Fig. 30.6).[118] Phosphorylation of eIF4E increases the binding affinity for mRNA caps to enhance translation initiation. Moreover, eIF4G is phosphorylated by S6 kinase, which enhances binding of mRNA to the 43S initiation complex (see Fig. 30.6).[119]

Although IIS enhances muscle protein synthesis, inhibition of protein degradation by IIS also controls proteostasis.[112,120] Proteins are degraded by the ubiquitin/proteasome or the autophagy/lysosome systems.[121] The proteasome is a multisubunit enzyme complex that coordinates degradation of ubiquinated proteins that control cell cycle, transcription, signaling, trafficking, and protein quality control.[122] The autophagy system, which is a less specific but highly regulated, engulfs portions of cytoplasm, organelles, glycogen, and protein aggregates in double-membrane vesicles that fuse with lysosomes.[100,122] Inhibition of IIS in skeletal muscle by gene deletion reduces muscle mass owing to more proteasomal and autophagy/lysosomal mediated degradation. Inactivation of FOXOs—FOXO1, FOXO3, and FOXO4—in skeletal muscles prevents muscle loss in response to prolonged fasting or inactivated IIS, because these transcription factors are required for the induction of several atrophy-related genes. Regardless, inhibition of autophagy might promote feedback insulin resistance through ubiquitination and proteasome-mediated degradation of IRS-1.[123]

Insulin-Regulated Glucose Transport

Glucose transport is the prototype insulin response that is rate limiting for dietary glucose utilization by muscle and adipose.[124,125] Members of the sodium-independent, facilitated-diffusion glucose/hexose transporter (GLUT) family are distinguished by substrate specificity and affinity, tissue distribution, and regulation. GLUT4 is the principal insulin-responsive glucose transporter that is expressed in white adipose tissue (WAT), brown adipose tissue (BAT), skeletal muscle, and heart, where it plays a direct role in glucose homeostasis. The molecular mechanisms linking the insulin signal to increased glucose influx involves complex multistep coupling between the signaling cascade and vesicle trafficking.[124,125]

Under basal conditions, GLUT4 accumulates in a general recycling compartment that, upon sorting, generates GLUT4 storage vesicles (GSVs) that form insulin-responsive vesicles (IRVs) that fuse with the plasma membrane in response to insulin[124-126] (Fig. 30.7). In addition to GLUT4, the GSVs contain other components, including sortilin, which mediates GLUT4 retrieval from trans-Golgi network and sorting endosomes to form the GSVs.[124]

Insulin acts at several sites to regulate GLUT4 translocation and recycling—including GSV assembly, release from intracellular retention sites, transport and fusion at the plasma membrane, and return. Insulin appears to promote dissociation of DGKζ·PIP5K1α (a complex of diacylglycerol kinase-ζ and phosphatidylinositol 4-phosphate 5-kinase 1a) from IRS1, which facilitates formation of the IRS1·PI3K complex to activate AKT and Rac family small GTPase 1 (RAC1) (see Fig. 30.7).[124,127] RAC1 may promote AKT membrane compartmentalization or actin remodeling to enhance insulin-stimulated GLUT4 translocation.[124]

Akt substrate of 160 kDa (AS160) and TBC1 domain family member 4 (TBC1D4) are GTPase-activating proteins that maintain their target RABs—including RAB8A, RAB10, RAB14, and others that regulate intracellular membrane flux—in an inactive GDP-bound state under basal conditions.[124,125] AKT phosphorylates and inhibits AS160 in adipose and TBC1Ds in muscle, which promotes RAB·GTP accumulation.[128,129] GTP-loaded RAB8A and RAB14 (muscle) or RAB10 (adipose) facilitates translocation of GSVs to the PM (see Fig. 30.7).[124,128] AKT2 phosphorylates and inactivates RAL·GAP, which leads to the accumulation and activation of RAL·GTP that binds to exocyst components—Sec5 and Exo70—to tether IRVs to the plasma membrane (see Fig. 30.7). Thus, insulin-stimulated AKT regulates translocation, docking, and fusion of GLUT4 vesicles with the plasma membrane.[124,128]

Insulin may regulate GLUT4 recycling back from the plasma membrane into an endocytic recycling compartment (ERC).[130] Formation of GLUT4 vesicles from the ERC relies upon a coat complex containing clathrin and ACAP1—an ARF6 GAP—that is recruited to ERC membranes by GRP1, an ARF6-GEF.[131] Budding of GSVs from the ERC is stimulated through the AKT-mediated phosphorylation of GRP1 (see Fig. 30.7).[132] Phosphomimetic mutations in GRP1 increase plasma membrane GLUT4 localization in 3T3-L1 white adipocytes, to a large degree bypassing the GLUT4 vesicle retention mechanisms.[132]

HETEROLOGOUS REGULATION OF INSULIN SIGNALING CASCADES

KEY POINTS

- Many mechanisms based upon heterologous regulation of gene expression and protein function exist to integrate and balance the InsR signal with other biological response. When these balanced signals are coopted by chronic inflammation or endoplasmic reticulum stress, insulin resistance can develop, which can progress to diabetes.

Proximal Insulin Signals

A couple of decades of genetic experiments in mice have established that changes in the relative function of a broad array of insulin signaling

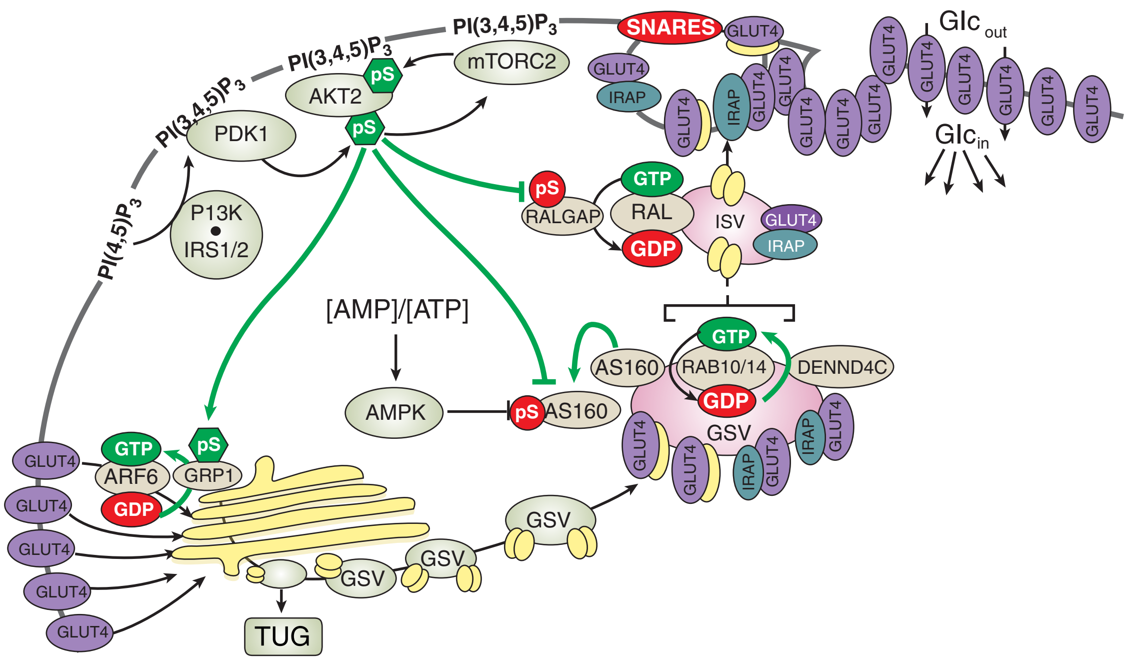

Fig. 30.7 **A mechanism of insulin-stimulated glucose transport by the PI3K→AKT→AS160/RALGAP/GRP1 branch of the insulin signaling pathway in adipose.** These AKT substrates mediate various steps of the assembly and trafficking of GLUT4 storage vesicles (GSVs). Endocytosis of GLUT4 cycles through the trans-Golgi network and is stimulated by AKT→GRP1·ARF6 signaling. AKT→AS160/RALGAP promotes translocation of the GSVs to the plasma membrane. Activation of these pathways by insulin promotes the accumulation of GLUT4-containing vesicles in the plasma membrane, which increases glucose influx.

components, nutrient sensors, and their downstream metabolic effectors can have profound effects upon insulin sensitivity, pancreatic β cell function, and nutrient homeostasis. Indeed, a 50% reduction in the concentration of the InsR IRS1, and IRS2 achieved by genetic means causes growth deficits and diabetes in mice[133]; however, physiologic mechanisms that regulate the concentration and function of proximal insulin signaling components are not understood well enough between tissues to guide the development of efficacious and safe treatments. For example, proximal IIS components can be regulated by yin yang 1 (YY1) in skeletal muscle or liver—including IGF1 and IGF2, IRS1 and IRS2, and AKT1, AKT2, and AKT3.[134,135] YY1 is a ubiquitous homeobox transcription factor that has diabetic (liver) or antidiabetic (skeletal muscle) effects, making it a challenging therapeutic target.

Transcriptional Control of Insulin Receptor Substrate 1

Recent work suggests that IRS1 expression may be regulated by transcriptional repressors, including AP2β or the p160 family of nuclear receptor coactivators p/CIP (p300/CBP/cointegrator-associated protein) and SRC1 (steroid receptor coactivator-1).[136,137] AP2β is expressed in adipose tissue where it promotes adipocyte hypertrophy, inhibits adiponectin expression, and enhances the expression of inflammatory adipokines such as IL6 (interleukin 6) and MCP1 (C-C motif chemokine ligand 2)[136] AP2β decreases IRS1 mRNA and protein concentration in adipocyte cell lines. Interestingly, GWAS reveals AP2β as a candidate gene for the risk of obesity and T2DM, which may involve negative regulation of IRS1 expression.[138] By contrast, p/CIP and SRC1 serve as transcriptional coactivators for nuclear hormone receptors and certain other transcription factors.[139] IRS1 expression increases upon inactivation of p/CIP and SRC1 in mice, which increases glucose uptake and enhanced insulin sensitivity in WAT and skeletal muscle. Finally, muscle-specific transcriptional coactivator with PDZ-binding motif (Taz) knockout mice display decreased IRS1 expression and insulin resistance.[140] Statins can reduce TAZ levels, which may reveal a mechanism of insulin resistance owing to decreased IRS1 expression; however, effects of statins upon protein prenylation might also be involved.[140]

Transcriptional Control of Insulin Receptor Substrate 2

IRS2 transcription is regulated by multiple factors, including CREB and its coactivator CRTC2, FOXO isoforms, HIF2α (hypoxia-inducible factor-2α encoded by EPAS1), NFAT (nuclear factor of activated T-cells), PGC1α, sterol regulatory element binding protein 1 (SREBP1c), signal transducer and activator of transcription 3 (STAT3), and transcription factor E3 (TFE3).[141-144] Multiple transcriptional mechanisms induce hepatic IRS2 expression during fasting, including nuclear FOXO that creates a direct feedback loop to augment insulin signaling during fasting and sensitively suppress it after a meal through AKT⊣ FOXO. Fasting or exercise also induce the CREB·CRTC2 transcriptional complex through glucagon signaling that increases expression of gluconeogenic genes along with IRS2.[142] Moreover, glucagon acting through PGC1α can increase hepatic IRS2 expression while suppressing IRS1, which can fine-tune gluconeogenesis and HGP during the fasting→feeding transition, with a minimal effect upon lipogenesis.[144] An E-box overlapping the FOXO site binds basic helix-loop-helix transcription factor E3 (TFE3), which converges with FOXO to promote IRS2 expression[145]; however, these elements also overlap with an SRE that binds sterol regulatory element binding transcription factor 1 (SREBF1), an important transcriptional activator of lipid synthesis.[146] Active hepatic SREBF1 increases during nutrient excess and chronic insulin stimulation, which decreases IRS2 expression to promote insulin resistance while promoting lipogenesis.[147,148] HIF2α is expressed in the hypoxic perivenous zone of the liver, where it restrains gluconeogenesis compared with other liver zones.[149,150] Thus, IRS2 expression is highly integrated through multiple metabolic sensors to promote insulin sensitivity and metabolic homeostasis.

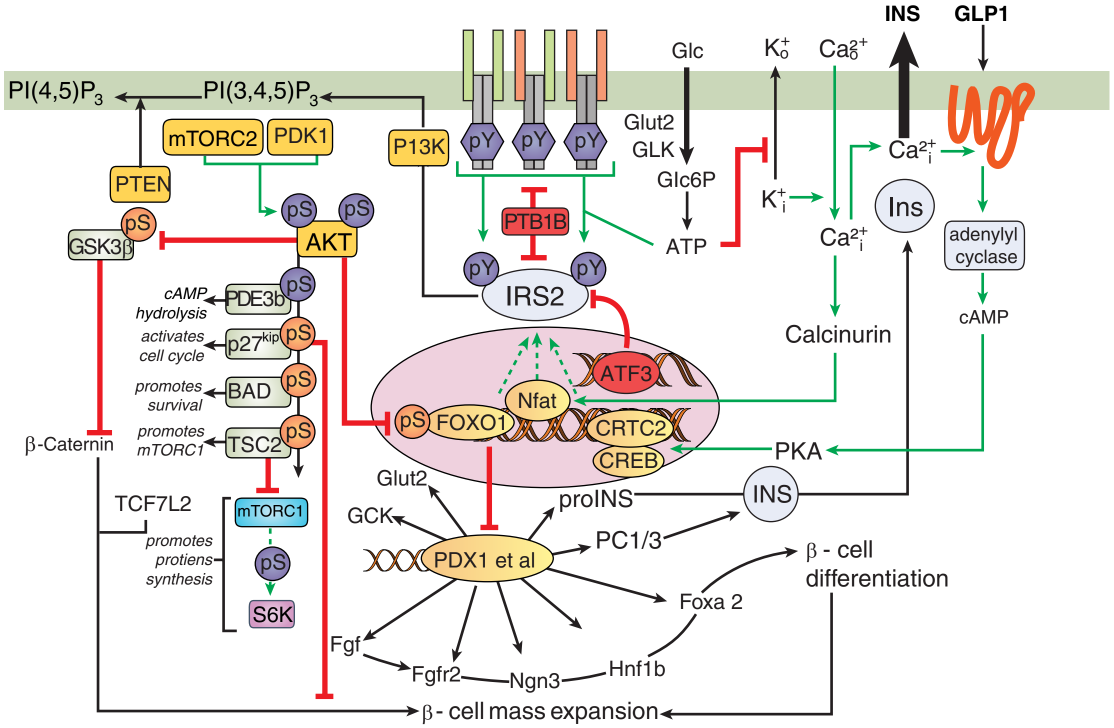

Fig. 30.8 **The integrative role of IRS2 signaling in pancreatic β-cell function.** The diagram shows the relation between the IRS2-branch of the insulin signaling pathway and upstream and downstream mechanisms regulating β-cell growth and function. Since InsR and IGF1R are constitutively active in β-cells, activation of GLP1→cAMP→PKA→CREB, glucose→Ca^{2+}→CRTC2, and calcineurin→NFAT induce IRS2 expression to regulate PI3K→AKT cascade, which places β-cell growth, function and survival under the control of glucose and incretins.

Regulation of Insulin Receptor Substrate Signaling by Ser/Thr Phosphorylation

IRS1 and IRS2 can be regulated through a complex mechanism involving phosphorylation of more than 50 serine/threonine residues (phospho-S/Ts) located in the long unstructured tail (see Fig. 30.5). Understanding how phospho-S/Ts regulate insulin signaling is challenging, because so many sites and mechanisms are involved.[151] Heterologous signaling cascades initiated by proinflammatory cytokines or metabolic excess—including TNFα (tumor necrosis factor-α), endothelin-1, angiotensin II, excess nutrients (free fatty acids, ceramides, amino acids and glucose) or endoplasmic reticulum stress—are implicated in IRS1/2 phospho-S/Ts, which associate with less insulin-stimulated tyrosine phosphorylation[151] These chronic heterologous mechanisms might contribute to glucose intolerance and pancreatic β-cell failure.[133] Regardless, most IRS1/2 phospho-S/Ts are stimulated by the PI3K→Akt→mTOR cascade during insulin stimulation.[151,152] Thus, IRS1/2 phospho-S/T is first and foremost a feedback mechanism that develops during chronic insulin stimulation, which can be coopted by metabolic stress to inhibit insulin signaling and dysregulate metabolic homeostasis (Fig. 30.8).[151] Thus, hyperinsulinemia may be the important physiologic mediator of insulin resistance in animals, and there is some experimental evidence that this is so.[153,154]

Mouse S307^{IRS1} (human S312^{IRS1}) is one of the best-studied phospho-S/Ts in IRS1, and is often used as barometer of insulin resistance.[151] Insulin can promote pS307^{Irs1} phosphorylation through the PI3K→AKT→mTORC1→S6K1 pathway (see Fig. 30.8).[152] In mice, free fatty acids promote pS307^{IRS1}, but insulin resistance and hyperinsulinemia are not excluded as the cause.[151] c-Jun N-terminal kinase (JNK1) or mTORC1 activated in obese mice promotes pS307^{IRS1} and other sites.[155,156] Although most, if not all, cell-based investigations support an inhibitory role for pS307^{IRS1}, mouse-based experiments are less convincing. Genetic knockin to replace S307^{IRS1} with alanine (A307^{IRS1}) increases fasting insulin and glucose levels while decreasing p110^{PI3K} binding to IRS1 PI3K.[157] During consumption of a high-fat diet, A307^{IRS1} mice exhibit more severe glucose intolerance and higher fasting insulin than control S307^{IRS1} mice. In mice, pS307^{IRS1} and other phospho-S/Ts may attenuate the detrimental effects of compensatory hyperinsulinemia to maintain a sensitive insulin response.[157] Careful analysis using molecular genetics is needed to establish the mechanisms involved.

Regulation of Insulin Receptor Substrate Degradation

Proteasome-mediated degradation regulates many biological processes including signal transduction, gene transcription, and cell cycle progression. Proteins targeted for destruction by the 26S proteasome are polyubiquitinated by various complexes composed of a ubiquitin-activating enzyme (E1), ubiquitin-conjugating enzyme (E2), and ubiquitin-protein ligase (E3).[158] IRS1 and IRS2 can be polyubiquitinated during chronic inflammatory states, nutrient excess, and hyperinsulinemia through various tissue-specific mechanisms.[159] The first pathway discovered involves suppressor of cytokine signaling 1 and 3 (SOCS1/3), which binds to IRS1 through its SH2 domain and to a ubiquitin E3 ligase through its SOCS box (see Fig. 30.9).[160,161] Mutations in the SOCS box prevent ubiquitinylation and degradation of IRS1 or IRS2,[160] and inhibition of SOCS1/3 expression by antisense oligonucleotides improves insulin sensitivity in obese and diabetic mice.[162] Cytokines like interferon gamma (INFγ) or IL6 activate Janus kinases (JAKs), which promote phosphorylation and dimerization of signal transducer and activator of transcription (STAT) factors that migrate into the nucleus to induce SOCS1/3 expression (see Fig.

30.9).[163] Angiopoietin-like 7 (Angptl7) also increases SOCS3 in obesity.[164] Thus, SOCS-mediated polyubiquitination of IRS1 or IRS2 can promote insulin resistance and glucose intolerance during infection, inflammation, or metabolic stress (see Fig. 30.9).

Other mechanisms of IRS degradation are coordinated by phospho-S/Ts. Cullin-RING E3 ubiquitin ligase 7 (CRL7) mediate IRS1 degradation downstream of phospho-S/T generated by the PI3K→AKT→mTORC1 cascade.[165] CRL7 complex contains cullin 7 (CUL7), a molecular scaffold that assembles F-box/WD repeat-containing protein 8 (FBW8) to recruit phosphorylated substrates, and RING-box protein 1 (Rbx1) associated with an E2-conjugating enzyme (see Fig. 30.9). FBW8 apparently binds to IRS1 through phospho-S/T residues generated by the mTORC1→S6K cascade—including human $pS307^{IRS1}$, $pS312^{IRS1}$, and $pS527^{IRS1}$, but possibly others—to mediate polyubiquitination of IRS1 that progresses to degradation (see Fig. 30.8).[165,166] This regulatory mechanism may be engaged during nutrient excess or hyperinsulinemia because it depends upon chronic hyperactivated mTORC1→SK6.[166]

Chronic consumption of high-calorie diets upregulates Cbl proto-oncogene B (CBLB), a RING-type E3 ubiquitin ligase that belongs to the casitas B-lineage lymphoma family of proteins.[111] CBL proteins share a conserved N-terminal region containing a tyrosine kinase–binding domain and a RING-finger domain to facilitate E3 ubiquitin ligase activity. Calorie excess induces carbohydrate-responsive element-binding protein (ChREBP) and SREBP1c, which upregulates myostatin (MSTN) in murine muscle to induce CBLB expression that drives insulin resistance through the polyubiquitination and degradation of IRS1.[167]

Regulation by Protein and Lipid Phosphatases

Phosphatases modulate IIS by dephosphorylating key proteins or lipids in the signaling cascade—including tyrosine-protein phosphatase nonreceptor type 1 (PTP1B, PTPN1), tyrosine-protein phosphatase nonreceptor type 2 (PTPN2, TCPTP), protein phosphatase 2A (PP2A), protein phosphatase 1 (PP1), phosphatase and tensin homolog (pTEN), tensin-like C1 domain-containing phosphatase (C1-TEN), and Src homology 2 domain–containing inositol 5′–phosphatase 2 (SHIP2). PTP1B and PTPN2 are related phosphotyrosine phosphatases that dephosphorylate various RTKs, including the bisphosphorylated regulatory loop of the InsR[168]; however, their biological effects can be distinct, owing to a different time courses, tissue expression, and substrate selection.[169] *Ptp1b*$^{-/-}$ mice display increased insulin sensitivity, lower circulating insulin concentrations, and decreased pancreatic β-cell mass.[170] Physiologically, both PTP1B and PTPN2 can be inactivated by reactive oxygen species generated during insulin stimulation.[47,171] In pancreatic β-cells, the IRS2→PI3K→AKT cascade is important for growth, function, and survival.[172] Thus, inactivation PTP1B can maintain β-cells mass in mice lacking IRS2, which prevents the early onset of diabetes.[172] Regardless, without IRS2 even the *Irs2*$^{-/-}$·*Ptp1b*$^{-/-}$ mice lose β-cell mass between 8 and 9 months of age as IRS1 signaling fails to compensate. PTP1B is a selective inhibitor of leptin signaling (LepRb→JAK2), as it dephosphorylates JAK2, whereas PTPN2 dephosphorylates JAK1⁄3 but not JAK2.[168] Central nervous system (CNS) inhibition of PTP1B can protect against obesity, whereas peripheral inhibition of PTP1B promotes glucose tolerance.[173] Inhibition of PTP1B or TCPTP in the brain, or specific hypothalamic neurons, promotes insulin and leptin signaling and prevents diet-induced obesity, T2D, and fatty liver disease.[174] Regardless, targeting PTP1B and TCPTP for treatment has been problematic because of challenges in targeting inhibitor to specific tissues; however, intranasal targeting of PTP1B and TCPTP can increase leptin and insulin sensitivity and promotes weight loss by repressing feeding and increasing energy expenditure.[175]

PTEN is a potent negative regulator of insulin action and cellular proliferation, and is a frequently mutated gene in human cancers.[176,177] PTEN attenuates IIS by dephosphorylating $PI(3,4)P_2$ and $PI(3,4,5)P_3$ at the 3-position, which reduces the recruitment and activation of PDK1, AKT, and others (see Fig. 30.8).[177] PTEN heterozygosity can increase peripheral insulin sensitivity in *Irs2*$^{-/-}$·*Pten*$^{+/-}$ mice and normalizes glucose tolerance, as the small islets in these mice produce enough insulin until death between 10 and 12 months age. These experiments highlight the complex relation between nutrient homeostasis, insulin sensitivity and secretion, and cancer that can emerge in rodents and humans.

Phosphatidylinositol-3,4,5-trisphosphate 5-phosphatase (SHIP2), encoded by the *INPPL1* gene, attenuates insulin signaling by dephosphorylating the 5′–position of PtdIns(3,4,5) (see Fig. 30.8). Several genetic studies link SHIP2 to metabolic disorders, showing that polymorphisms in *INPPL1* may contribute to the pathogenesis of the metabolic syndrome, hypertension, and T2DM.[178] Despite this complexity, inhibition of SHIP2 may have therapeutic value. Metformin may increase insulin sensitivity by inhibiting SHIP2, which enhances glucose uptake while protecting renal podocytes from apoptosis in diabetic rodent models.[179]

Phosphoserine-directed phosphatases—including PP2A and PP1—have complex effects depending upon substrate targeting. PP2A is a widely expressed Ser/Thr protein phosphatase that forms a heterotrimeric complex with scaffold and regulatory subunits to target various subcellular locations and substrates.[180] PP2A can be a negative regulator of insulin's metabolic signaling by dephosphorylating and inactivating AKT or dephosphorylating and activating GSK3b.[181,182] PP2A also targets phospho-S/Ts in IRS1, which stabilizes IRS1 for tyrosine phosphorylation to enhance IIS.[183,184] PP1 also targets and dephosphorylates IRS1, which can promote IIS. Phosphoproteomic analysis of L6 skeletal muscle cells reveals the interaction of myosin phosphatase targeting subunit 1 (MYPT1)—a targeting subunit of protein phosphatase 1catalytic subunit beta (PP1cβ) with IRS1.[185] Activation of the MYPT1·PP1 complex by PKA promotes dephosphorylation of serine residues in IRS1 to increase tyrosine phosphorylation and stimulate PI3K→AKT cascade.[186]

miRNA-Mediated Posttranscriptional Regulation

miRNAs are short (~20 nucleotides) noncoding RNA molecules that negatively modulate gene expression through their specific binding within the 3′ untranslated region sequence of mRNA to inhibit translation or destabilize the target mRNA. Most of the proximal components of IIS can be regulated in a tissue-specific way by miRNAs.[187] LET7 miRNA interferes with many proximal IIS components—including IGF1R, InsR, IRS2, PIK3IP1, AKT2, TSC1, and RICTOR.[188] LET7 interference can be inhibited by the RNA-binding proteins Lin28a and Lin28b, which block production of mature LET7 to increase translation of the insulin signaling components. LET7 associates with gigantism, puberty delay, and glucose homeostasis by modulating insulin→PI3K→mTOR signaling and insulin sensitivity.[188]

Many other miRNAs display specificity against proximal IIS components during metabolic challenge in various tissues. Hepatic miR-424-5p, miR-15b, miR-195, and miR-96 increase in mouse liver on a high-fat diet, which associates with less InsR expression.[189-192] IRS1 and IRS2 are targeted by miRNAs in multiple peripheral insulin target tissues: miR-222 can suppress IRS1 in liver and adipose during high-fat diet and sucrose feeding[193]; resistin upregulates miR-145 to inhibit IRS1 levels[194]; miR-29a and miR-29c suppress IRS1 expression in muscle of T2DM patients or mice fed a high-fat diet[195]; and IRS1 can be downregulated in mouse endothelial cells by miR-126, which dysregulates angiogenesis.[196] Chronic angiotensin-II induced hypertension can increase the expression of miR-487b in rat aorta, which suppresses IRS1 expression and promotes hypertension-induced cardiovascular disease and formation of aortic aneurysms owing to the loss of medial smooth muscle.[197]

IRS2 expression is also suppressed by various miRNAs. The miR-126 targets IRS2 in pancreatic β cells, which can suppress islet growth.[198] Upregulation of miR-33b reduces hepatic IRS2→AKT signaling, whereas miR-135a reduces IRS2→AKT signaling in muscle of T2DM patients and *db/db* mice.[199] miR-26b appears to suppress PTEN to promote GLUT4 translocation in adipose and β cell function during obesity.[200] Other proximal IIS components are also modulated by various miRNAs—including SHIP2 (miR-205-5p), PDK1 (miR-375), AKT (miR-143—| ORP8), PP2A (miR-19b, miR-429, miR-29, and miR-155), and IGF1R.[187] Animal models suggest that modulating miRNA expression *in vivo* may be a beneficial strategy to restore insulin sensitivity and prevent the progression of T2DM.[201]

MOUSE GENETICS REVEAL TISSUE-INTEGRATED INSULIN SIGNALING

Introduction

KEY POINTS

- Genetic experiments in mice provide a robust and rigorous experimental platform to understand the role of insulin signaling throughout the body.

During the past 25 years, investigators used genetically manipulated mice to establish the molecular and integrated physiology of insulin action. Whole-body deletion of InsR, Irs proteins, or Akt isoforms confirmed the importance of IIS for metabolic and growth regulation. While informative, metabolic interactions between the various tissues complicates analysis of whole-body gene deletion. Thus, Cre-loxP technology was employed to investigate—albeit not perfectly—the role of InsR→Irs→Akt—| FoxO1 signaling in specific tissues or organs.[202,203] Even tissue-specific knockouts have limitations, as the elimination of IIS is rarely involved in common metabolic disease. Moreover, dysregulated insulin action in specific target tissues can influence metabolic regulation throughout the organism owing to crosstalk by secreted peptides, metabolites, or neuronal interconnections.[204,205] Regardless, Cre-loxP technology continues to be valuable to dissect IIS cascades.

Systemic Insulin Receptor Signaling Cascade

InsR and IGF1R have overlapping and distinct effects during development and adult life. Mice without InsR or the IGF1R die for different reasons shortly after birth.[206] IGF1R-deficient mice are born 50% smaller than normal littermates and die after a few days owing to developmental defects.[207] By contrast, mice lacking the InsR have nearly normal size but less adipose tissue mass at birth. InsR-deficient mice die a few days after birth with severe hyperglycemia, severe pancreatic failure, and ketoacidosis.[208] Thus, IGF1/2→IGF1R signaling is the principle growth regulatory pathway in fetal mice, whereas insulin→InsR signaling is essential for postnatal nutrient homeostasis.[209] InsR-deficient mice can be rescued genetically by transgenic expression of the InsR in the brain, liver, and pancreatic β cells.[210] Unlike mice, humans lacking functional InsR display intrauterine growth retardation, failure to thrive, and hypoglycemia for weeks until hyperglycemia develops.[209] This paradox may involve limited availability of gluconeogenic substrates or extreme hyperinsulinemia that may activate enough IGF1 receptors to generate some insulin-like actions.[211]

Work with transgenic and whole-body knockout mice confirms that the vast majority, if not all, of IIS is mediated through the IRS proteins.[212] IRS1 and IRS2 can display unique signaling properties in various tissues, apparently owing to different expression, receptor coupling, or regulation.[213] Systemic deletion of Irs1 produces small, insulin-resistant mice with nearly normal glucose homeostasis owing to β cell expansion and lifelong compensatory hyperinsulinemia.[214] These results suggest that mouse Irs1 is not essential for β cell growth during insulin resistance. By contrast, mice in which Irs2 is deleted display nearly normal body growth and even gain fat mass; however, male *Irs2*$^{-/-}$ mice develop life-threatening diabetes after 8 weeks of age owing to the progressive loss of β cell mass that disrupts compensatory hyperinsulinemia.[215] Female mice develop diabetes more slowly, and many, but not all, develop severe hyperglycemia by 6 months.[216] Compound deletion of Irs1 and Irs2 appears to be embryonic lethal; however, littermates retaining one allele of *Irs1* (*Irs1*$^{+/-}$•*Irs2*$^{-/-}$) or one allele of *Irs2* (*Irs1*$^{-/-}$•*Irs2*$^{+/-}$) can be born alive.[217] *Irs1*$^{+/-}$•*Irs2*$^{-/-}$ mice develop severe fasting hyperglycemia and die by 4 weeks of age as β cells fail to grow or survive. By contrast, *Irs1*$^{-/-}$•*Irs2*$^{+/-}$ mice are very small but have enough circulating insulin for glucose tolerance.[217] Thus, mouse Irs1 and Irs2 are essential for development and nutrient homeostasis, and some Irs2 is essential for β cell growth function and survival.

Hepatic InsR—| FoxO1 Signaling

The liver in an important site of insulin action that plays a role in systemic glucose and lipid homeostasis.[202] InsR$^{L/L}$·Cre^{Alb} (LIRKO; hepatic albumin Cre driver) mice display moderately elevated fasting glucose and severe postprandial hyperglycemia and glucose intolerance.[218] LIRKO mice also develop severe hyperinsulinemia owing to a combination of increased insulin secretion and reduced hepatic insulin degradation.[219] LIRKO mice display reduced levels of circulating free fatty acids and triglycerides on ordinary chow diets[202,218]; however, when fed an atherogenic diet, LIRKO mice develop dyslipidemia that can progress to atherosclerosis.[220] InsR deletion dysregulates hundreds of hepatic genes, including reduced glucokinase, hexokinase 4 (GCK) and elevated phosphoenolpyruvate carboxykinase 1 (PCK1), G6PC, and pyruvate kinase (PK1).[202,218] Chronic hyperinsulinemia in LIRKO mice exacerbates peripheral insulin resistance, whereas streptozotocin injections to reduce insulin secretion improve peripheral insulin resistance but fail to suppress HGP.[221] Thus, heterologous mechanisms dysregulated by hepatic insulin resistance—including the systemic effects of hyperinsulinemia—may exacerbate HGP through indirect mechanisms that may promote adipose insulin resistance and delivery of excess glycerol and nonesterified fatty acids (NEFAs) to the liver for HGP.[205,222,223]

For over a decade, we have modeled hepatic insulin resistance by genetic inactivation of hepatic Irs1 and Irs2 in LDKO (Irs1$^{L/L}$·Irs2$^{L/L}$·Cre^{Alb}) mice[205,224-226]. LDKO mice display unsuppressed HGP, hyper insulinemia, glucose intolerance, and diabetes.[205,224-226] At first, these results suggest that hepatic Irs1/2 mediate systemic nutrient homeostasis through hepatic insulin signaling; however, WAT, BAT, and skeletal muscle are also insulin-resistant in LDKO mice, suggesting that dysregulated hepatic metabolism manifests systemically.[205,227] Remarkably, metabolic health is restored upon hepatic inactivation of FoxO1 in LTKO (LDKO·FoxO1$^{L/L}$) mice, even though the liver is mechanistically unresponsive to insulin.[205,224-227] These findings are confirmed and extended with compound hepatic-specific InsR·FoxO1- or Akt1·Akt2·FoxO1-knockout mice.[90,228-230] Clearly, genetic disruption of hepatic FoxO1 substantially normalizes the expression of hundreds of dysregulated hepatic genes.[90,224] Within such mice, FoxO1-dependent gene expression or metabolites generated in hepatocytes and circulating systemically could promote peripheral insulin resistance and the delivery of metabolic intermediates to the liver—including excess glycerol and free fatty acids from adipose tissue.[231] Comprehensive analyses of the LDKO- and LTKO-mice revealed that follistatin (Fst)—best known for its modulation of TGF-β superfamily members[232,233]—is a key FoxO1-dependent hepatokine that can promote WAT lipolysis during hepatic insulin resistance.[205] Thus, while failing to restore hepatic insulin signaling *per se*, disruption of hepatic FoxO1 in LTKO mice and similar models may restore glucose tolerance by normalizing hepatokine secretion.[224,228,229,234]

Insulin and Insulin-Like Growth Factor Signaling and Glucose Homeostasis In Skeletal Muscle

IIS in skeletal muscle is initiated by the activation of the insulin and/or IGF1 receptor tyrosine kinases, which can exist as hybrids linked to the downstream pathways through the IRS1 and IRS2 branches of the cascade.[235] Some, but not all, aspects of metabolic disease emerge upon deletion of skeletal muscle InsR in MIRKO (InsR$^{L/L}$·Cre^{Mck}; muscle creatine kinase Cre driver) mice—including mild obesity and elevated circulating free fatty acids and triglycerides; however, glucose and hyperinsulinemia never develop.[202,236] Moreover, deletion of InsR and IGF1R in MIGIRKO (InsR$^{L/L}$·IGF1R$^{L/L}$·Cre^{ACTA1}; human skeletal muscle actin Cre driver) mice results in more than 60% less muscle mass, while glucose and insulin tolerance remain normal, owing, at least in part, to increased basal glucose uptake.[237] Consistent with these results, MDKO (Irs1$^{L/L}$·Irs2$^{L/L}$·Cre^{Mck}) mice also fail to develop hyperglycemia and glucose intolerance during progressive and fatal skeletal and cardiac muscle autophagy.[113] Akt phosphorylation is completely lost in MDKO mice, suggesting that InsR/IGF1R signaling is its major agonist.[113] Isolated skeletal muscles from MDKO mice show elevated basal but absent insulin-stimulated glucose uptake, while glucose metabolism shifts to lactate production—which elevates the AMP/ATP ratio to stimulate AMP-activated protein kinase (AMPK) phosphorylation of AS160/Tcb1D4 and TBC1D! and insulin-independent glucose uptake (see Fig. 30.7).[113]

By comparison, muscle-specific deletion of GLUT4 *(Slc2a4)* dysregulates glucose homeostasis and promotes systemic insulin resistance to a greater extent than deletion of proximal insulin signaling components.[238] MG4KO (GLUT4$^{L/L}$·Cre^{Mck}) mice develop hyperglycemia, glucose intolerance, and insulin resistance by 8 weeks of age.[239] These mice also display dysregulated glucose metabolism in adipose and liver. Hyperglycemia owing to diminished muscle glucose utilization appears to drive heterologous insulin resistance, because normalization of circulating glucose by kidney excretion can restore insulin action in adipose and liver.[238,240]

Insulin and Insulin-Like Growth Factor Signaling in Cardiac and Vascular Smooth Muscle

MDKO (Irs1$^{L/L}$·Irs2$^{L/L}$·Cre^{Mck}) mice display cardiac arrest between 3 and 4 weeks of age owing to severe left ventricular failure.[113] Because a single allele of either *Irs1* or *Irs2* in cardiac muscle can prevent sudden death, we conclude that either Irs1 or Irs2 mediates enough IIS to prevent excess autophagy and fatal cardiac muscle loss.[113] Regardless, pressure overload–induced cardiac hypertrophy and heart failure are associated with insulin resistance and hyperinsulinemia, which can exacerbate left ventricular remodeling.[241] Reducing cardiac insulin signaling by lowering circulating insulin or reducing InsR→AKT1 signaling can attenuate heart failure.[242] Experiments with CIrs1KO (Irs1$^{L/L}$·Cre$^{\alpha rer}$; myosin, heavy polypeptide 6, cardiac muscle, alpha Cre driver) or CIrs2KO mice suggest that Irs1 may promote a proinflammatory response following pressure overload.[241] CIrs1KO hearts display less Akt1 activity and mild cardiac hypertrophy during pressure overload; however, CIrs2KO hearts display severe cardiac dysfunction that can be attenuated by *Akt1* haploinsufficiency.[241] Thus, IIS→IRS1 signaling can exacerbate heart failure in mice, which may explain how hyperinsulinemia during T2DM aggravates cardiovascular disease.

Vascular disease is a major cause of morbidity associated with insulin resistance and T2DM owing to a greater risk of myocardial infarction compared against normal individuals.[243] Endothelial cells (ECs) and vascular smooth muscle cells (VSMCs) are the major constituents of medium- and large-sized arteries with essential functions in vascular homeostasis. The progression of atherogenesis can involve dysregulated crosstalk between immune cells, ECs, and VSMCs.[244] Specific deletion of InsR or IGF1R in VSMCs show that InsR—but not IGF1R—mediates VSMC proliferation and intimal hyperplasia following intimal injury.[245] The PI3K→AKT cascade phosphorylates eNOS, which promotes vascular relaxation to optimize blood flow (see Fig. 30.6). Without the endothelial InsR, atherosclerotic lesion size increases more than 2-fold in atherosclerosis-prone apolipoprotein E–deficient (*Apoe*$^{-/-}$) mice.[246] Moreover, the extent of the aortic intima occupied by the lesion increases in *Irs2*$^{+/-}$·*ApoE*$^{-/-}$ mice compared with *ApoE*$^{-/-}$ mice.[247] Deletion of myocardial InsR can decrease VEGF expression and capillary density and reduce reactive angiogenesis during ischemia reperfusion damage or myocardial infarction.[248] Because Irs2 is more abundant than Irs1 in endothelial cells, endothelial cell–specific Irs2 knockout (ETIrs2KO) impairs eNOS phosphorylation, muscle insulin delivery, and glucose uptake.[203,249] Taken together, managing InsR→IRS2 signaling in the endothelium may benefit cardiovascular complications.

Adipose Insulin Signaling

Insulin signaling promotes adipogenesis and stimulates glucose influx, lipid synthesis, and antilipolysis in mature adipose.[250] WAT is important for the storage of postprandial glucose as triglyceride and the secretion of signaling factors that regulate appetite and energy homeostasis.[154,251] WAT mainly expresses IRB without detectable IGF1R; however, both receptors play a role in adipogenesis. Interpretation of genetic deletion of adipose Insr$^{L/L}$ is complicated by the Cre drivers used to generate the various experimental mice—including Cre^{aP2} (FIRKO mice; fatty acid binding protein 4 Cre driver) verses Cre^{Adipo} (F-IRKO mice; adiponectin Cre driver).[252,253] FIRKO mice display variable recombination efficiency in fat depots with some off-target events, whereas F-IRKO mice have more efficient InsR deletion across fat depots with few or no off-target effects.[254] With respect to these caveats, FIRKO mice display beneficial metabolic effects, including systemic insulin sensitivity, normal glucose tolerance, and less fat mass on ordinary chow diets.[252] FIRKO mice also have a longer lifespan, suggesting that leanness and insulin sensitivity are associated with longevity.[255] By contrast, F-IRKO mice display lipodystrophy with hepatomegaly, steatosis, and increased enzymes of *de novo* lipogenesis.[253] F-IRKO mice develop a full spectrum of NAFLD that can progress to NASH, fibrosis, and liver dysplasia—which is more in line with the expected effects of adipose insulin resistance.[154] These phenotypes are exacerbated upon compound deletion of InsR and IGF1R by Cre^{Adipo}, which promotes lipodystrophy of WAT and BAT accompanied by diabetes, insulin resistance, increased β cell mass, and ectopic lipid accumulation.[254] Thus, the InsR appears to be essential for the formation and maintenance of WAT, whereas both InsR and IGF1R contribute to BAT mass development and thermogenesis.

Insulin-regulated GLUT4-mediated glucose transport is rate-limiting for glucose influx into adipose tissues under normal glucose and insulin concentrations. GLUT4 translocation to the plasma membrane is extremely sensitive to insulin in adipocytes, as submaximal activation of AKT2 is enough to maximally stimulate glucose transport. Before high-fat diet–induced insulin resistance inhibits AKT phosphorylation, GLUT4 translocation is strongly inhibited, suggesting that decreased glucose utilization may reside downstream of proximal IIS and AKT activity.[154] Increased adipose GLUT4 expression can rescue systemic insulin resistance of mice fed the high-fat diet.[256]

Adipose triacylglycerol (TAG) storage is regulated by circulating factors with opposing effects on lipolysis—β-adrenergic receptors (βAR1/2/3) and insulin. Activation of βAR1/2/3 stimulates cAMP production to promote PKA-mediated phosphorylation of perilipin 1 (PLIN1), which releases abhydrolase domain–containing 5 (ABHD5) to fully activate patatin-like phospholipase domain–containing 2 (ATGL/PNPLA2), hydrolyzing one fatty acid from TAG.[257] PKA also phosphorylates hormone-sensitive lipase (HSL) to promote its translocation to PLIN1 to hydrolyze FA from diacylglycerol (DAG) and produce monoacylglycerol, which is hydrolyzed by monoacylglycerol lipase (MGL) to release the final FA and glycerol.[258] Insulin inhibits lipolysis to promote fatty acid storage as TAG in adipose lipid droplets[258,259]; however, the mechanism is only partly understood, as deletion of AKT2 only partly impairs the ability of insulin to suppress lipolysis.[258,260] Regulated lipolysis is critical, as it controls the delivery of NEFA and glycerol to the liver, which stimulates HGP.[154] Insulin inhibits lipolysis by promoting hydrolysis of cAMP via an uncertain mechanism. Originally, AKT was thought to activate PDE3b by phosphorylation; however, the direct phosphorylation of PDE3B by AKT might not be required.[260] Instead, AKT phosphorylates ab hydrolase domain-containing protein 15 (ABHD15), which binds and stabilizes PDE3B for the antilipolytic action of insulin.[258,261,262]

Insulin Receptor Substrate 2 as a Gateway to β Cell Function

The capacity of pancreatic β cells to maintain glucose homeostasis during chronic physiologic and immunologic stress is important for cellular and metabolic homeostasis.[263] Pancreatic β-cells have a special place in nutrient homeostasis as the unique source of insulin secretion, and like other cells require IIS for growth, function, and survival (see Fig. 30.8). β cells appear to be regulated by multifactor transcriptional control of IRS2 through the action of FOXO1/3, NFAT, and CREB•CRTC2 (see Fig. 30.8).[264] In β-cells, FOXO can account for as much as 80% of the basal IRS2 expression[265]. Because the IRS2→PI3K→AKT cascade phosphorylates and inhibits FOXO, insulin or IGF1 have inhibitory effects upon FOXO-mediated transcription of IRS2. Because β-cell mass and function must be protected during chronic nutrient excess that provokes excess insulin secretion, other mechanisms—especially glucose-stimulated Ca^{2+} influx and cAMP production— promote IRS2 expression to avoid progressive β-cell failure (see Fig. 30.8). In addition to its immediate role in insulin secretion, glucose→calcium influx activates calcineurin, which dephosphorylates NFAT to facilitate its entry into the nucleus, where it induces expression of *IRS2* and other genes (see Fig. 30.8).[266] Glucose, GLP1 (glucagon-like peptide-1) and other GPCR agonists also increase the cAMP in β-cells, which has many important effects, including the activation of CREB·CRTC2 that promotes *IRS2* transcription.[267,268] Through this mechanism, the role of insulin/IGF1 to trigger downstream IIS in β-cells is replaced by indirect control through glucose, incretins, or neuronal signals—the physiologically relevant regulators of pancreatic β-cell function (Fig. 30.8). IRS2 expression through these mechanisms maintains PDX1 action, which is essential for β cell growth, function, and survival.[269] Compounds that augment IRS2 expression may provide treatments for β cell failure during insulin resistance and the progression of T2DM.[263]

Insulin/IGF Signaling in Neurodegenerative Disease

Insulin resistance associated with obesity promotes T2DM, cardiovascular disease, certain cancers and—with aging—cognitive decline and Alzheimer's disease and related dementia (ADRD).[19,270,271] How dysregulated brain IIS or peripheral insulin resistance and its metabolic sequelae promote cognitive decline is unclear and difficult to study.[19,272,273] In the brain, IRS1, IRS2, and IRS4 link IRA, insulin-like growth factor-1 receptor (IGF1R), and their hybrids (IRA•IGF1R) to downstream pathways that mediate IIS. Neurotrophic tyrosine kinase (TrkA) and TrkB—which regulate synaptic strength and plasticity—also engage IRS in neurons.[274,275] Regardless, mechanisms linking peripheral insulin resistance and central IIS to cognitive decline and ADRD are elusive. Numerous factors regulate the strength or duration of IIS, including variable expression, stability, and localization of the proximal downstream components—IRS1/2/4, PI3K, and AKT1/2.[134,276,277]

Central IIS, modified by peripheral insulin sensitivity, provides an important link between metabolic health and sustained hippocampal function.[19,270] Impaired central IIS in Alzheimer's disease brain samples,[278,279] as well as mouse models of Alzheimer's disease,[280] suggests that enhanced central IIS could be therapeutic—a hypothesis that has prompted nasal delivery of insulin to treat ADRD.[270] Clinical studies associate neuronal pS/T^{IRS1} in humans with ADRD[278,280,281]—but the mechanistic basis and import of these observations for central insulin resistance remain unclear.[152,157,282]

The role of central IIS is unsettled because reducing IIS→Irs2 may increase lifespan and promote memory formation in mice[283-286]—even while producing obesity, peripheral insulin resistance, and hyperinsulinemia.[215,283,287-291] Similarly, decreased *Irs2* gene dose improves motor performance and extends lifespan in R6/2 Huntington disease model mice, associated with reduced neuronal oxidative stress and enhanced autophagy and mitochondrial function.[292] Less Irs2 also increases nuclear FoxO1 in R6/2-mice,[292] which may prevent age-related axonal degeneration.[293]

An important question is whether IIS→IRS modulates adult hippocampal neurogenesis directly or through peripheral metabolic dysregulation. New neurons are continuously generated in the dentate gyrus (DG) of the hippocampus.[294-296] DG neurogenesis in humans can persist into the ninth decade of life—but declines in ADRD.[297,298] Newly formed neurons may sustain and enhance memory or facilitate further memory acquisition—including better "pattern separation" and spatial memory.[295,299,300] DG neurogenesis is augmented by physical activity and extrinsic (e.g. TNFα, TGFβ, INFγ, insulin/IGF[296,301]) or intrinsic factors (Sox2, Hes1/5, REST, FoxOs, NeuroD1, CREB, Prox1). DG neurogenesis measurably improves rodent learning in the Morris water maze,[302] so it will be important to understand the role of IIS in these processes. Thus, a fuller investigation of hippocampal IIS is warranted, along with behavioral experiments that reveal effects of peripheral IIS on learning and memory.

INSULIN RESISTANCE AND METABOLIC DISEASE

Introduction

KEY POINTS

- It is challenging to understand the molecular basis of insulin resistance, because physiologic mechanisms like hyperinsulinemia and hyperglycemia are tightly integrated with multiple signaling cascades, dyslipidemia, inflammatory cytokines, endoplasmic reticulum stress, and hepatokine secretion.

Insulin resistance is considered the fundamental trigger of T2DM; however, transient insulin resistance may be a feedback mechanism to protect cells and tissues from acute effects of overnutrition.[154,303] Regardless, significant gaps exist in our knowledge of the molecular mechanisms that cause insulin resistance and the progression of T2DM. Several pathologic mechanisms associated closely with overnutrition and inactivity promote insulin resistance and T2DM—including compensatory hyperinsulinemia and β cell dysfunction; InsR and

IRS1/2 degradation; elevated circulating glucose, circulating NEFA, and dysregulated proteostasis; local or circulating proinflammatory cytokines, adipokines, myokines, or hepatokines; oxidative and endoplasmic reticulum (ER) stress; and endothelial dysfunction.[11,304,305] Regardless, in humans and animals it is challenging to understand the mechanistic hierarchy and their integration for disease progression.

Clinical staging suggests that early insulin resistance in skeletal muscle—the primary site of glucose disposal in humans—may initiate the progression of T2DM.[111] Compatible with this hypothesis, healthy human subjects who display skeletal muscle insulin resistance exhibit decreased incorporation of glucose into muscle glycogen and increased hepatic triglyceride synthesis[306]; however, animal models of pure skeletal muscle insulin resistance—including mice that lack muscle InsR, IGF1R or Irs1/2—show surprisingly mild glycemic changes.[113,236] Thus, uncoupled effector systems such as insulin-stimulated glucose influx and oxidation—rather than dysregulated proximal InsR signaling—may emerge as the cause of metabolic disease.[154] Moreover, hepatic insulin resistance plays an important role in uncontrolled HGP, but how cell-autonomous mechanisms—including impaired IRS1/2 or AKT1/2 phosphorylation—and dysregulated interorgan metabolic flux and communication contribute are unresolved.[90,204,205,218,307]

Chronic Hyperinsulinemia

Chronic overnutrition and inactivity are usually associated with obesity and insulin resistance that can progress to T2DM when sufficient insulin is unavailable to promote nutrient storage and suppress HGP. The mechanisms are difficult to resolve, because insulin resistance triggers hyperinsulinemia, which in turn promotes insulin resistance and obesity.[154] Chronic compensatory hyperinsulinemia overactivates the IR→IRS cascade that can promote feedback mechanisms to downregulate the cell-surface InsR concentration and uncouple IRS→PI3K→AKT from its effector systems (Fig. 30.9). As obesity progresses, hepatic IRS2 expression decreases due to hyperinsulinemia, which impairs insulin signaling in the liver.[308] As the IRS2:IRS1 ratio falls, IRS1 continues

IRS Degradation

Fig. 30.9 Schematic diagram of heterologous and feedback regulation of insulin signaling. Various kinases in the insulin signaling cascade mediate feedback inhibition of IRS, including PKB, mTOR, S6K, ERK, AKT, and atypical PKC isoforms.[152] Other kinases activated by heterologous signals, including lipids such as ceramide, are also involved. Adiponectin signaling may promote insulin signaling by driving the conversion of ceramide to nontoxic sphingosine. Serine phosphorylation of IRS1 can recruit CRL7, which can promote ubiquitinylation and degradation of IRS1 through the 26S proteasome. Many proinflammatory cytokines cause insulin resistance through SOCS1 or SOCS3, which target phosphotyrosine-containing proteins like IRS1 or IRS2 for ubiquitination by a BC-containing ubiquitin ligase (E3) and degradation.[347-349]

to drive hepatic lipogenesis, unless feedback mechanisms further inhibit IR→IRS1 signaling.[226] Hepatic insulin resistance can accelerate hyperinsulinemia to impair insulin signaling in other tissues as well. Although various mechanisms are probably involved, hyperglycemia can provoke pancreatic β cell mass expansion by glucose→calcium→NFAT–mediated IRS2 expression.[309] The important role of hyperinsulinemia to promote insulin resistance is validated by reduced weight gain and better glucose tolerance in mice with genetically attenuated hyperinsulinemia during chronic high-fat diet feeding.[153,154,310]

Nutrient Excess

The struggle to store excess nutrients by nonoxidative disposal as muscle glycogen or adipose triglyceride can promote metabolic disease and T2DM.[11] Even while elevated average insulin may promote enough muscle glycogen storage to defend against hyperglycemia, it can increase hepatic lipogenesis, WAT expansion, and hepatic steatosis.[11] The accumulation of nutrient-derived toxic metabolites—including NEFA, DAG, or ceramides—within insulin-sensitive tissues can activate novel PKC isoforms that mediate Ser/Thr phosphorylation of INSR or IRS1, inhibiting the proximal signaling cascade.[305] Moreover, while insulin action decreases, NEFA and glycerol flux from insulin-resistant adipose can promote liver gluconeogenesis by mass action and allosteric mechanisms that exacerbate average circulating glucose and insulin secretion.

Nutrient excess and progressive insulin resistance can dysregulate muscle proteostasis to exaggerate circulating branched-chain amino acids levels, which stimulate mTORC1→S6K/GRB10 activity that can further inhibit IR→IRS1/IRS2 signaling.[311,312] Chronic mTORC1 activity also promotes synthetic processes that exacerbate ER stress, activating an unfolded protein response that can cause insulin resistance.[17,313-315] Thus, chronic mTORC1 activity by amino acid excess can feedback inhibit the InsR→IRS1/IRS2 cascade to impair glycogen storage (muscle) and antilipolysis (WAT) while stimulating hepatic lipogenesis to promote T2DM.

Proinflammatory Cytokines

Low-grade chronic inflammation occurs in adipose tissue, liver, pancreatic islets, vasculature, and circulating leukocytes during obesity and T2DM.[17,304,316] The expanding adipose compartment creates a microenvironment conducive to inflammation owing to hypoxia, adipose cell death, and dysregulated adipokines, including decreased adiponectin and increased leptin, resistin, and RBP4.[303,317] Proinflammatory M1-like adipose-tissue macrophages (ATMs) accumulate in expanding WAT[318] and contribute to local and circulating concentrations of proinflammatory cytokines—including monocyte chemoattractant protein 1 (MCP1), interleukin 6 (IL6), and TNFα (tumor necrosis factor-α.[319,320] TNFα promotes glucose intolerance, and both TNFα and IL6 can induce lipolysis.[320]

TNFα can promote insulin resistance during nutrient excess and obesity as it activates JNK1 (Jun N-terminal Kinase-1) and IKKβ (inhibitor of nuclear factor kappa B kinase subunit beta) in insulin-sensitive tissues.[304,305] JNK appears to co-opt feedback mechanisms ordinarily activated by chronic hyperinsulinemia, especially S/T-phosphorylation of IRS1.[151,152] Inhibition of JNK activity in obese mice using kinase inhibitors increases insulin sensitivity and improves glucose homeostasis; moreover, Jnk1-deficient mice are protected from obesity and insulin resistance caused by high-fat diet feeding.[155,321] Regardless, tissue-specific Jnk1 ablation in various peripheral tissues—including adipose, liver, muscle, and myeloid—does not reduce obesity; however, genetic deletion of TNFα in the CNS reduces energy expenditure that associates with increased iodothyronine 5'-deiodinase (DIO2).[322] High-fat diets cause JNK-mediated DIO2 expression, which decreases the hypothalamic–pituitary–thyroid (HPT) axis and promotes obesity.[323] Regardless, administration of TNFα inhibitors to insulin resistant humans does not improve glucose homeostasis, despite reduction in some parameters of systemic inflammation.[324] Thus, the physiologic relevance of the TNFα→JNK cascade as a cause of insulin resistance in humans remains unclear.[305]

Cytokines can have contradictory effects upon metabolic regulation. During acute injury, IL6 secreted from T-cells and macrophages is beneficial, as it mobilizes stored nutrients from muscle and adipose tissues to provide substrates and energy to fight infection and repair tissue.[320,325] Moreover, physical activity promotes the secretion IL6 from skeletal muscle, which can mediate anti-inflammatory and immunoregulatory effects to reduce circulating TNFα.[325] Infusion of recombinant human IL6 into healthy individuals enhances whole-body insulin sensitivity, fat oxidation, and reesterification of NEFAs.[325,326] Chronic genetic overexpression of IL6 in mice fed a high-fat diet reduces daily food consumption, adiposity, and circulating leptin, while increasing energy expenditure.[327] Although IL6 stimulates the STAT3→SOCS3 cascade—which can inhibit IR→IRS1 signaling—it protects hepatic IR→IRS2 signaling in mice fed a high-fat diet to improve hepatic insulin sensitivity.[327] Thus, although circulating IL6 increases in genetically diabetic LDKO mice ($Irs1^{L/L}\cdot Irs2^{L/L}\cdot Cre^{Alb}$), it has no beneficial effect without Irs2.[205]

Hepatic Follistatin Links Liver and White Adipose Tissue Insulin Resistance

Proteins exclusively or predominantly produced and secreted from a specific tissue can have paracrine or endocrine actions. Adipokines are perhaps the best-known, although other classes of tissue-specific secreted proteins have been identified—including myokines, lipokines, and hepatokines.[350] Over the past decade, evidence points to a dysregulated pattern of hepatokine secretion, which directly affects metabolism.{Stefan, 2013, 23337953} Recent work suggests that FOXO1-induced hepatic follistatin (FST) can upregulate HGP by promoting WAT insulin resistance and lipolysis.[205] Viral suppression of hepatic Fst in LDKO ($Irs1^{L/L}\cdot Irs2^{L/L}\cdot Cre^{Alb}$) mice restores WAT insulin sensitivity and glucose tolerance, whereas its over-expression in livers of wild-type or healthy LTKO ($LDKO\cdot FoxO1^{L/L}$) mice has opposite effects.[205] Thus, excess hepatic Fst impairs glucose homeostasis regardless of the state of hepatic insulin signaling. These data add to the growing body of evidence that hepatokines can drive peripheral insulin resistance, which promotes T2DM.[329-331]

FST may be the first hepatokine identified to induce adipose tissue lipolysis, thereby shifting NEFA and glycerol from WAT to the liver.[332] Subjects in the Tübingen Family Study/Tübingen Lifestyle Program cohort were interrogated to establish the relation between FST and nutrient homeostasis in patients.[332,333] Magnetic resonance was used to estimate body fat distribution, and ^1H–magnetic resonance to estimate liver fat content.[330] FST, glucose, insulin, and NEFA were measured in serum, and an oral glucose tolerance test (OGTT) was used to measure whole-body insulin sensitivity (IS_{body}) and adipose insulin sensitivity ($IS_{adipose}$).[333] Univariate analysis shows that circulating FST is independent of sex and age but positively associated with body mass index ($r = 0.27$, $P = .0001$), total body fat mass ($r = 0.28$, $P < .0001$), visceral fat mass ($r = 0.18$, $P = .008$), liver fat content ($r = 0.23$, $P = .0008$), and circulating NEFA during the OGTT at 0 minutes ($r = 0.22$, $P = .001$), 60 minutes ($r = 0.28$, $P < .0001$), and 120 minutes ($r = 0.28$, $P < .0001$).[332] After adjusting for age, sex, and total body fat mass, $IS_{adipose}$ correlates negatively with circulating FST. Moreover, liver fat content correlates positively with circulating FST (standard $\beta = 0.17 \pm 0.07$, $P = .009$); however, this correlation disappeared after adjusting for leg fat mass ($r = 0.09 \pm 0.06$, $P = .14$).[332] Thus, FST may impair IS_{adipo} in leg fat—an important compartment of benign fat storage.[334,335] FST also increases significantly in subjects with NAFLD, suggesting that impaired IS_{adipo} may shift NEFA to the liver to promote NAFLD.[336,337]

Endoplasmic Reticulum Stress and the Unfolded Protein Response

The ER is a network of interconnected membrane-enclosed tubes that are continuous with the outer membrane of the nuclear envelope. Smooth ER lacks ribosomes and functions in lipid and cholesterol biosynthesis, carbohydrate metabolism, and detoxification; rough ER is coated with ribosomes, where protein synthesis is especially prominent.[338,339] In many cases, disulfide bond formation contributes to protein folding, which requires nutrient homeostasis to support an oxidizing environment.[340] The unfolded protein response is activated when circumstances disrupt protein folding, including glucose and energy deprivation, cholesterol accumulation, viral infection, and other factors that dysregulate protein synthesis.[338,339] Distinct branches of the unfolded protein response are initiated by type-I transmembrane kinases—PKR-like endoplasmic reticulum kinase (PERK) and inositol requiring enzyme-1 (IRE1)—and activating transcription factor-6 (ATF6).[338,339] In the liver, PERK reduces global protein synthesis by phosphorylating eIF2a, while selective translation can lead to obesity and insulin resistance.[341,342] IRE1 signaling activates JNK in the liver and adipose tissues to increase Ser/Thr phosphorylation of IRS1.[343] ATF6 upregulates expression of the X-box binding protein 1 (XBP1) transcription factor to increase the protein folding capacity that compensates during protein overload. ATF6→XBP1 also interacts with FOXO1 to direct it toward proteasome-mediated degradation, which can contribute to systemic insulin sensitivity.[344] Attenuation of ER stress in obese and diabetic mice through the use of chemical chaperones—agents that promote ER folding capacity—improves insulin sensitivity and glucose tolerance.[345,346]

Classification and Diagnosis of Diabetes Mellitus

Aoife M. Egan and Sean F. Dinneen

OUTLINE

Definition, 524
Classification, 524
- Type 1 Diabetes, 525
- Type 2 Diabetes, 526
- Other Specific Types of Diabetes, 527
- Genetic Defects in **β** Cell Function, 527
- Genetic Defects in Insulin Action, 529
- Diseases of the Exocrine Pancreas, 529
- Endocrinopathies, 529
- Drug- or Chemical-Induced Diabetes, 529
- Infections, 530
- Uncommon Forms of Immune-Mediated Diabetes, 530
- Other Genetic Syndromes Sometimes Associated with Diabetes, 530
- Gestational Diabetes, 530

Diagnosis, 531
- Diagnostic Criteria, 531
- What Level of Fasting Plasma Glucose Constitutes Diabetes?, 532
- What Level of Fasting Plasma Glucose Constitutes Normality?, 532

What's New?, 534

DEFINITION

The term *diabetes mellitus* does not represent a single disease entity, but rather a set of disease states that share certain characteristics. Foremost among these is the presence of elevated plasma glucose levels. As is discussed in the following section, the presence of hyperglycemia in a patient is used both to diagnose diabetes and to guide management decisions, which are directed largely toward avoiding hyperglycemia. The hyperglycemia itself results from a combination of defects in insulin secretion, insulin action, or both.[1] An important characteristic of the various disease states that are labeled as diabetes is the development of end-organ damage in vital organs of the body, including the retina, the renal glomerulus, and peripheral nerves. Damage results, at least in part, from the long-term effects of hyperglycemia and is mediated through glycation of tissue proteins, increased activity of the polyol pathway, or other, as yet unrecognized, mechanisms.[2] Individual patients vary in their predisposition to develop these so-called microvascular complications. Because of this and because of the length of time they take to develop (frequently decades), the complications of diabetes cannot be used to classify or diagnose the disease. People with diabetes are at considerably greater risk of developing atherosclerotic disease affecting the coronary, cerebrovascular, peripheral arterial, or other parts of the circulation. A cause-and-effect relationship between chronic hyperglycemia and these so-called macrovascular complications of diabetes has not been as clearly established, although evidence linking the two is accumulating.[3] Any definition of diabetes that refers only to carbohydrate metabolism is incomplete. Oskar Minkowski is reputed to have first identified the association between the insulin-deficient pancreatectomized state of his laboratory dogs and the sweet taste of their urine. It has been suggested that if Minkowski had lacked a sense of taste but possessed a keen sense of smell, he might have smelled the ketones on the breath of his animals and thereby directed diabetes research toward the study of fat metabolism.[4] Disordered fat and protein metabolism must be included in a complete definition of the disease, although an emphasis on the pathogenesis of hyperglycemia continues to this day. To define a disease purely in biochemical terms is to diminish the component of the disease that leads to much physical, mental, and psychosocial distress for the many millions of people around the world who live with it every day. Chronic rheumatic diseases such as rheumatoid arthritis are not associated with any biochemical hallmark, and their definition is based largely on patient-reported symptoms and physical signs. Therefore, it is important not to forget the patient's perspective in any "definition" of the chronic disease referred to as diabetes.

KEY POINTS

- Diabetes mellitus represents a heterogeneous set of disorders that share raised plasma glucose levels as their defining characteristic.

CLASSIFICATION

Before 1979, a classification system for diabetes was not well established, and many different terms were used to describe essentially the same clinical entity. Following publication that year of the report of the National Diabetes Data Group (NDDG),[5] some order was brought to bear in this area. The recommendations of the NDDG were subsequently endorsed by the World Health Organization (WHO) in a publication in 1980, and minor modifications were later made in a document published in 1985.[6] This classification in large part was based on pharmacologic treatment of the disease. Insulin-dependent diabetes mellitus (IDDM) and non–insulin-dependent diabetes mellitus (NIDDM) were the two major forms of diabetes that had been identified. The term *IDDM* was used to describe patients who typically were lean at presentation, were prone to ketosis, and required insulin for survival. The term *NIDDM* was used to describe patients who typically were overweight or obese at presentation, were not prone to ketosis, and did not require insulin for survival. The NDDG also had categories for gestational diabetes and malnutrition-related diabetes mellitus (MRDM) and a category labeled “other types,” which included certain forms of diabetes for which a cause had been suggested at that time. As the terms *IDDM* and *NIDDM* became widely used during the 1980s and 1990s, several problems became apparent. The main problem arose from the fact that many patients with NIDDM ended up at some point in the course of their disease being treated with insulin and being misclassified as having IDDM or having the rather confusing term *insulin-requiring NIDDM* applied to them. In addition, as more information became available on the causes of the various forms of diabetes, it became apparent that a classification based on therapy was not always consistent with new insights into the pathogenesis of the various forms of diabetes. For this reason, the American Diabetes Association (ADA) convened an expert panel in 1995 to address the issue of classification. This panel published its recommendations in 1997,[7] and these were subsequently endorsed by a WHO consultation group in a 1998 report.[8] The main thrust of this proposal was to move away from a classification based on therapy and toward one based on pathogenesis. Four major categories were proposed: type 1 diabetes, type 2 diabetes, other specific types of diabetes (including categories for which a cause has been established), and gestational diabetes. The details of this classification system, which are outlined in Table 31.1 (with contemporary updates), are discussed in the following sections.[9]

KEY POINTS

- The major categories of diabetes mellitus include type 1 diabetes, type 2 diabetes, gestational diabetes, and other specific types of diabetes. Accurate classification informs the best therapeutic interventions.

Type 1 Diabetes

Type 1 diabetes is characterized by the development of a state of complete insulin deficiency arising as a consequence of β cell destruction. In its fully developed form, people with this condition, if deprived of exogenous insulin, will develop ketoacidosis, coma, and death. Biochemical testing reveals a marked reduction or complete absence of circulating C-peptide (a marker of insulin secretion) despite hyperglycemia. In 2009, approximately 167,000 youth were living with type 1 diabetes in the United States, with 18,000 new cases diagnosed each year.[10] While prevalence and incidence data among adults in the

TABLE 31.1 **Classification of Diabetes Mellitus**

1. Type 1 diabetes
    A. Immune-mediated
    B. Idiopathic
2. Type 2 diabetes
3. Other specific types
    A. Genetic defects in β cell function
        1. Maturity onset diabetes of the young (MODY) 1–14
        2. Neonatal diabetes
        3. Mitochondrial DNA
        4. Others
    B. Genetic defects in insulin action
        1. Donohue syndrome
        2. Rabson Mendenhall syndrome
        3. Type A insulin resistance
        4. Lipodystrophic diabetes
    C. Diseases of the exocrine pancreas
        1. Pancreatitis
        2. Trauma/pancreatectomy
        3. Neoplasia
        4. Cystic fibrosis

        11. Others
4. Gestational diabetes mellitus

Adapted from the Report of the Expert Committee on the Diagnosis and Classification of Diabetes Mellitus. *Diabetes Care*. 1997;20:1183–1197.

United States are limited, information collected by the 1999–2010 National Health and Nutrition Examination Survey estimates that 740,000 to 970,000 Americans are affected.[11] Although the peak incidence is in childhood and early adolescence, this form of diabetes can occur at any age. The incidence of the disease shows marked regional variation, with the highest worldwide incidence reported in parts of Scandinavia.[10] Epidemiologic and immunologic research have led to the recognition of two major forms of type 1 diabetes based on the presence or absence of certain immunologic markers.

Autoimmune Type 1 Diabetes. Autoimmune type 1 diabetes is a prototypic organ-specific autoimmune disorder. Individuals who develop this form of diabetes are born with a genetic predisposition to autoimmune dysfunction, which may manifest in the development of other autoimmune conditions such as Addison disease, vitiligo, pernicious anemia, Hashimoto thyroiditis, or celiac disease. The genetic predisposition is not well understood but is known to be linked to the major histocompatibility locus on chromosome 6.[12] The presence of certain human lymphocyte antigen (HLA) haplotypes appears to predispose the individual to the disease, while other HLA haplotypes appear to be protective. In predisposed individuals, a poorly understood environmental trigger sets off a series of immunologic events that culminate in selective T-cell–mediated destruction of the β cells of the pancreatic islet. Many antigens have been investigated as potential triggers for the disease with inconclusive results. These include certain viral antigens,[13] as well as an antigen contained in cow's milk protein[14] and gluten.[15] A large series of investigations has been carried out for the "Diabetes Autoimmunity Study in the Young." These studies initially investigated the early detection of antiislet antibodies in children[16] and their role in the prediction of future type 1 diabetes.[17,18] The rate at which β cell destruction occurs varies from individual to individual and may be very brief, as is seen when type 1 diabetes presents in children or young adults,[18,19] or may be prolonged, as is seen in what has been called *latent autoimmune diabetes* in adults.[20] The rate of progression also depends on the number of autoantibodies, antibody specificity, and autoantibody titer.[21,22] Antibodies appear in the circulation early in the process of β cell destruction.[23] In type 1 diabetes, autoantibodies are believed to be markers (rather than true instigators) of the immune response, and, as already alluded to, our understanding of the precise immunology is limited. An ongoing clinical study will examine blood samples from those who develop type 1 diabetes at a very young age in the hope that studying those with extreme forms of the disease will facilitate discovery of specific pathologic mechanisms.[24]

The presence of autoantibodies can help to classify a newly diagnosed patient with diabetes, and screening for these autoantibodies has led to recognition of autoimmune type 1 diabetes in individuals who otherwise may have been labeled as having type 2 diabetes[25] (see later). Islet cell antibodies, the first autoantibodies to be discovered, are directed against a range of islet antigens. The best characterized autoantibodies are those directed against glutamic acid decarboxylase (GAD), an enzyme that is involved in γ-aminobutyric acid synthesis.[26] Isoforms of GAD are found in the central nervous system and in β cells of the pancreatic islet. Other autoantibodies include those directed against tyrosine phosphatases, namely IA-2 and IA-2β, as well as antibodies directed against zinc (ZnT8) and insulin itself (antiinsulin antibodies). Autoantibodies are present in 85% to 90% of individuals with type 1 diabetes at the time of presentation with fasting hyperglycemia.[16] Childhood-onset type 1 diabetes is associated with higher levels of autoantibody in serum. Testing for these autoantibodies is still restricted to a limited number of laboratories. The ADA states that autoantibodies are not required for the routine diagnosis of diabetes, but agree that standardized autoantibody tests can be used for classification of diabetes.[27] They also advise that screening for type 1 diabetes risk with a panel of islet autoantibodies is an option for a first-degree family member of a person with type 1 diabetes. In this situation, persistence of autoantibodies is a risk factor for progression to diabetes and may facilitate intervention in the setting of a clinical trial.[27]

Idiopathic Type 1 Diabetes. The term *idiopathic type 1 diabetes* is used to describe a small subset of individuals with type 1 diabetes who appear not to have an autoimmune basis for their β cell destruction.[28] Other features of this subtype include its occurrence predominantly in individuals of Black American or Asian ethnicity, its lack of HLA association, and its intermittent proneness to ketosis. A number of different terms, including *atypical diabetes, Flatbush diabetes,* and *type 1.5 diabetes,* have been used to describe this form of diabetes. The preferred term in the recent literature appears to be *ketosis-prone type 2 diabetes.*[29]

KEY POINTS

- Type 1 diabetes is characterized by total insulin deficiency. While this is typically caused by autoimmune destruction of the β cells in predisposed individuals, a minority will have idiopathic type 1 diabetes.

Type 2 Diabetes

Type 2 diabetes represents the most common form of diabetes. The number of adults with type 2 diabetes has doubled over the past three decades. Current estimates for the US population indicate that over 30 million people have type 2 diabetes,[30] while worldwide estimates for type 2 diabetes reach over 400 million.[31] The condition is characterized by hyperglycemia that arises from defects in insulin secretion and action, impaired glucose effectiveness, and impaired postprandial suppression of glucagon.[32,33] In any given individual, the degree to which these defects contribute to hyperglycemia may vary. The disease usually has its onset after 40 years of age, although type 2 diabetes is being seen increasingly in young adults and adolescents.[34] Although progressive β cell failure is believed by many to be an important part of the natural history of this form of diabetes,[35] the β cell destruction is not autoimmune-mediated[1] and typically does not progress to the point at which the patient becomes dependent on insulin for survival. Ketoacidosis is unusual in this form of diabetes, and, when it occurs, it usually does so in the setting of a major intercurrent illness such as myocardial infarction or stroke, or when the patient is undergoing treatment with certain drugs such as glucocorticoids or sodium-glucose cotransporter 2 inhibitors.[36] Individuals with type 2 diabetes are not at increased risk for autoimmune disease, but have a higher prevalence of metabolic abnormalities, including obesity, hypertension, and a dyslipidemia that is characterized by hypertriglyceridemia and low levels of high-density lipoprotein cholesterol. This combination of metabolic derangements is associated with a marked increase in risk for atherosclerotic disease. In fact, the prevalence of atherosclerotic disease in individuals with type 2 diabetes has led to the suggestion that, rather than one leading to the other, the two conditions may share common antecedents.[3] Insulin resistance may be an important predisposing factor for both conditions. An inflammatory paradigm of innate immune cell activation has been proposed as an underlying factor for both conditions.[37]

The cause of type 2 diabetes remains to be determined. Any pathogenetic model of the disease must include both genetic and environmental factors. Challenges in establishing the cause of type 2 diabetes include the following: (1) The disease lacks an easy-to-define phenotype and instead is characterized by considerable heterogeneity across different ethnic groups; this heterogeneity often is represented by a spectrum ranging from a predominant defect in insulin secretion on the one hand to a predominant defect in insulin action on the other. (2) The relatively late age of onset makes it difficult to establish large kindreds, and therefore limits genetic studies. (3) No easy-to-apply methods are available for screening populations for insulin resistance and defective insulin secretion. (4) The pathways that are involved in mediating insulin action are complex and are not fully understood; most authors believe that a single genetic defect will explain only a subset of the disease; it is much more likely that type 2 diabetes represents a set of disorders. Evidence to support a genetic component of the disease comes from the strong concordance for the disease that is seen among monozygotic twins.[38] On the other hand, the dramatic increase in incidence and prevalence of type 2 diabetes that accompanies the change to a so-called Westernized lifestyle strongly supports an environmental component as well.[39]

KEY POINTS

- Type 2 diabetes is the most common form of diabetes and is associated with defects in insulin secretion and action, impaired glucose effectiveness, and impaired postprandial glucagon suppression. Although progressive β cell failure is a feature of this condition, most patients are not dependent on insulin for survival.

Other Specific Types of Diabetes

Other specific types of diabetes are included in both the 1979 NDDG and the 1997 ADA classification systems.[5,7] Several changes occurred in the subtypes of diabetes listed between the two eras. In particular, monogenetic diabetes syndromes, including neonatal diabetes and maturity-onset diabetes of the young (MODY), have been better defined genetically; and the classification of monogenic diabetes has evolved from one based on clinical characteristics to one based on molecular genetics. While updates are reflected annually in the ADA Standards of Medical Care in Diabetes, this is a rapidly evolving area, and further changes to existing classification systems are anticipated.[27] Another change from the original 1979 classification system resulted from removal of MRDM and inclusion of fibrocalculous pancreatic diabetes (which was previously a subtype of MRDM) as a disease of the exocrine pancreas. The decision to remove MRDM as a separate entity resulted from an international conference on this subject.[40,41] The findings of the conference did not support a direct cause-and-effect relationship between protein-calorie malnutrition and the development of diabetes. Rather, it was thought that the presence of malnutrition could influence the manner in which diabetes might present in an otherwise predisposed individual.

Genetic Defects in β Cell Function

In the past, the term *MODY* was used to describe a subset of patients with a form of diabetes characterized by early age of onset of hyperglycemia with an autosomal dominant mode of inheritance. Mutations in certain genes that are involved in regulating insulin secretion have now been shown to be responsible for the hyperglycemia seen in MODY kindreds.[42] A karyogram of the various MODY mutations is shown in Fig 31.1. To date, 14 forms of MODY have been described,[43] and their clinical and genetic features are outlined in Table 31.2 (see Chapter 49). All forms of MODY are associated with defective insulin secretion without any significant degree of insulin resistance.[44,45] In the case of the most common subtype, GCK-MODY (MODY2), the

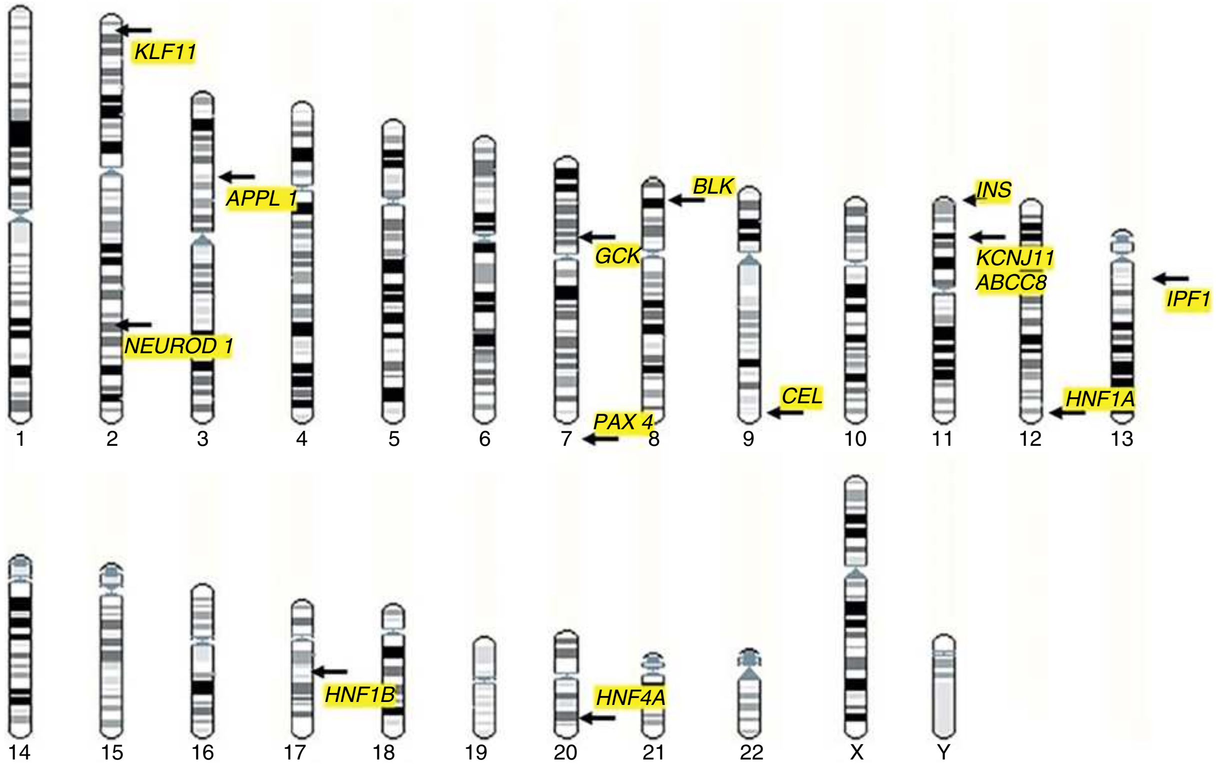

Figure 31.1 **Karyogram of the common and rare forms of maturity-onset diabetes of the young (MODY) mutations.** (From Aarthy R, Aston-Mourney K, Mikocka-Walus, et al. Clinical features, complications and treatment of rarer forms of maturity-onset diabetes of the young (MODY)—a review. *J Diabetes Complications*. 2021;35:107640.)

TABLE 31.2 Maturity-Onset Diabetes of the Young (MODY)-Related Genes and the Clinical Phenotypes Associated With Mutations in the Genes

MODY Type	Gene	Clinical Features of Heterozygous State	Most Common Treatment	Molecular Basis	Clinical Features of Homozygous State
MODY 1	*HNF-4α*	May have high birth weight and transient neonatal hypoglycemia; diabetes; microvascular complications (in many cases); reductions in serum concentrations of triglycerides, apolipoproteins AII and CIII, and Lp(a) lipoprotein	Sensitive to sulfonylurea drugs	Abnormal regulation of gene transcription in β cells, leading to a progressive defect in metabolic signaling of insulin secretion, β cell mass, or both	
MODY 2	Glucokinase	Impaired fasting glucose, small rise in 2-hour plasma glucose on oral glucose tolerance test	Diet and exercise, insulin therapy may be required during pregnancy	Nonprogressive defect in sensitivity of β cells to glucose due to reduced glucose phosphorylation; defect in hepatic storage of glucose as glycogen	Permanent neonatal diabetes requiring insulin treatment
MODY 3	*HNF-1α*	Diabetes, microvascular complications (in many cases), renal glycosuria, increased sensitivity to sulfonylurea drugs	Low-dose sulfonylureas, insulin	Abnormal regulation of gene transcription in β cells, leading to a progressive defect in metabolic signaling of insulin secretion, β cell mass, or both	
MODY 4	*IPF-1*	Diabetes	Oral hypoglycemic agent, insulin	Abnormal transcriptional regulation of β cell development and function	Pancreatic agenesis and neonatal diabetes requiring insulin treatment
MODY 5	*HNF-1β*	Diabetes; renal cysts and other abnormalities of renal development; progressive nondiabetic renal dysfunction, leading to chronic renal insufficiency and failure; internal genital abnormalities (in female carriers)	A minority respond to sulfonylurea drugs, Insulin	Abnormal regulation of gene transcription in β cells, leading to a defect in metabolic signaling of insulin secretion, β cell mass, or both	
MODY 6	NeuroD1 or *BETA2*	Diabetes, neonatal diabetes	Insulin	Abnormal transcriptional regulation of β cell development and function	Neurological abnormalities
MODY 7	*KLF11*	Diabetes	Oral hypoglycemic agent, insulin	Abnormal *PDX1* transcription in the β cell	
MODY 8	*CEL*	Diabetes +/-exocrine pancreas dysfunction, associated with increased risk of diabetic kidney disease	Insulin	Abnormal endocrine and exocrine pancreas regulation	
MODY 9	*PAX4*	Diabetes with increased risk of microvascular complications	Oral hypoglycemic agent, insulin required for the majority	Abnormal regulation of gene transcription in β cells	
MODY 10	*INS*	Diabetes	Oral hypoglycemic agent, but usually requires insulin	Insulin gene mutation, defective insulin secretion	
MODY 11	*BLK*	Diabetes and obesity	Oral hypoglycemic agent, insulin	Defect in insulin production	
MODY 12	*ADCC8*	Diabetes	Sensitive to sulfonylurea drugs, insulin may be required	Defect in insulin release	
MODY 13	*KCNJ11*	Diabetes	Sensitive to sulfonylurea drugs	Defect in insulin release	Neonatal diabetes
MODY 14	*APPL1*	Diabetes, may have developmental delay	Oral hypoglycemic agent, insulin	Defect in insulin secretion	

BETA2, β cell Ebox transactivator 2; *HNF,* hepatocyte nuclear factor; *IPF,* insulin promoter factor; *MODY,* maturity-onset diabetes of the young; *NeuroD1,* neurogenic differentiation factor 1.

From American Diabetes Association: Diagnosis and classification of diabetes mellitus. *Diabetes Care*. 2021;44:S15-S33; and Aarthy R, Aston-Mourney K, Mikocka-Walus, et al. Clinical features, complications and treatment of rarer forms of maturity-onset diabetes of the young (MODY) - A review. *J Diabetes Complications*. 2021;35:107640.

pathophysiologic mechanism is clear, because the affected enzyme is involved in phosphorylating glucose, one of the first steps in glucose metabolism. A glucokinase mutation therefore decreases the ability of the β cell to sense glucose. MODY2 is associated with relatively mild hyperglycemia that is best left untreated. MODY1 and MODY3, on the other hand, can be associated with more severe hyperglycemia, a greater likelihood that insulin will be required for management, and a higher propensity to develop complications.[42] The link between diabetes and mutations in the genes for hepatocyte nuclear factor (HNF)-1a, HNF-1β (hepatocyte transcription factors also expressed in β cells), and HNF-4a (a member of the steroid-thyroid hormone superfamily and an upstream regulator of HNF-1a), appears to involve regulation of expression of the insulin gene.[46] As screening for MODY is typically physician-based rather than population-based, the majority of cases remain misclassified, and it has been suggested that MODY may account for between 2% and 5% of cases of type 2 diabetes.[47] In the United Kingdom, the marked regional variation in the prevalence of confirmed MODY directly results from differences in referral rates and likely reflects access to specialized centers with genetic testing.[48]

Neonatal diabetes occurs in children under 6 months of age. It is rare and may be transient or permanent.[49] Several genetic defects have been identified in these patients. Transient neonatal diabetes is typically due to overexpression of genes on chromosome 6q24, and, most notably, mutations in the adenosine triphosphate (ATP)-sensitive potassium channel (KATP) of the β cell cause permanent diabetes.[50] The KATP channel comprises two subunits (Kir6.2 and SUR1), and mutations in these can result in loss of function (leading to channel closure and neonatal hyperinsulinemic hypoglycemia) or gain of function (leading to channel opening and neonatal diabetes). Although rare, elucidation of these conditions and the molecular mechanisms underlying them has improved our understanding of this area of human biology. Moreover, diabetes arising from KATP channelopathies can retain sensitivity to the insulin secretagogue effects of sulfonylureas.[51]

Other genetic disorders that are associated with impaired β cell function include certain maternally inherited forms of diabetes with a mutation in mitochondrial DNA,[52] disorders that lead to impaired conversion of proinsulin to insulin,[53] and disorders that lead to synthesis of an aberrant form of the insulin molecule.[54] Of the former conditions, diabetes associated with an A-to-G transition at nucleotide 3243 in mitochondrial transfer RNA has been best characterized and appears to have a wide phenotypic expression from type 2 through to type 1 diabetes. The latter two conditions are inherited in an autosomal dominant manner and are associated with relatively mild glucose intolerance.

As genetic testing has become more accessible, the ADA now recommends that all children diagnosed with diabetes in the first 6 months of life have genetic testing for neonatal diabetes. They further advise that children and young adults who have diabetes not characteristic of type 1 or 2 diabetes that occurs in successive generations should have genetic testing for MODY.[27]

Genetic Defects in Insulin Action

Insulin resistance is closely associated with type 2 diabetes and, while commonly found in those with obesity, may rarely occur in a severe form in people with genetic variations. Semple et al. propose two major categories of syndromes of severe insulin resistance: (1) primary insulin-signaling defects, and (2) insulin resistance secondary to adipose tissue abnormalities (including syndromes of severe obesity and lipodystrophy, the latter of which is frequently associated with diabetes mellitus).[55] Abnormal glucose homeostasis, ovarian dysfunction, and acanthosis nigricans are features that occur in nearly all forms of insulin resistance; however, other manifestations including dyslipidemia and hepatic steatosis are limited to specific subtypes.[55]

Insulin receptor defects include Donohue syndrome (formerly "leprechaunism") and Rabson Mendenhall syndrome.[56,57] Both syndromes are autosomal recessive, present within the first decade of life, and are associated with diabetes, hyperinsulinemia, and altered growth. More commonly, insulin receptor defects occur later in life with an autosomal dominant inheritance pattern and features of oligomenorrhea, hyperandrogenism, and acanthosis nigricans.[55] This includes syndromes that were previously named HAIR-AN (hyperandrogenism, insulin resistance, and acanthosis nigricans in females) and type A insulin resistance (severe insulin resistance in nonobese patients).[58,59] Of note, type B insulin resistance is a term used to describe acquired insulin resistance in the presence of anti–insulin receptor antibodies (see later).

Lipodystrophy is characterized by pathological adipose tissue deficiency with multiple subtypes. Broadly speaking, lipodystrophy may be partial or generalized, and inherited or acquired (see Chapter 24).[60] Lipodystrophy should be included in the differential diagnosis in severely insulin-resistant patients with dyslipidemia and/or nonalcoholic fatty liver disease.[55] The use of genetic testing in the classification of genetic syndromes of insulin action remains an area for evaluation within subspecialized services at this time.

Diseases of the Exocrine Pancreas

Hyperglycemia can occur during an episode of acute pancreatitis and is associated with a poor prognosis. It is unusual for permanent diabetes to develop following a single episode of acute pancreatitis. Furthermore, removal of up to 90% of the pancreas does not always cause diabetes. On the other hand, diabetes has been reported in association with very small pancreatic adenocarcinomas, leading some investigators to speculate that these tumors produce some diabetogenic factor or factors.[61] Five to fifteen percent of patients with cystic fibrosis develop diabetes.[62] Insulin replacement in cystic fibrosis–related diabetes (CFRD) is often challenging, as these individuals retain insulin sensitivity and are prone to hypoglycemic episodes. Moreover, insulin requirement in the setting of CFRD is complicated by malabsorption and the associated need for enteral feeding, as well as by infectious exacerbations associated with underlying bronchiectasis.[63] Hemochromatosis can cause diabetes.[64] Because glucose tolerance may improve with venesection, this condition represents an important, potentially reversible cause of diabetes. Fibrocalculous pancreatic diabetes is seen mainly in the tropics and is associated with abdominal pain and calcification of the pancreas on abdominal imaging.[65] The natural history of this form of diabetes has been established,[66] along with a genetic marker of the disease.[67]

Endocrinopathies

Cortisol, growth hormone, glucagon, and the catecholamines (epinephrine and norepinephrine) can antagonize insulin action. Tumors that produce these hormones in excess lead to Cushing syndrome, acromegaly, glucagonoma, and pheochromocytoma, respectively. Although all of these conditions are associated with a degree of glucose intolerance, overt diabetes develops only in a subset of patients. The importance of recognizing these secondary forms of diabetes lies in the fact that resection of the underlying tumor can cure diabetes. The hyperglycemia that is seen in the setting of aldosterone-producing adenomas and somatostatinomas results from alteration of insulin secretion. An added challenge to diabetes mellitus arising from endocrinopathy is that somatostatin analogs often used to control conditions such as growth hormone excess and, more recently, glucocorticoid excess can induce diabetes in their own right (described in the following section).

Drug- or Chemical-Induced Diabetes

While the development of immune checkpoint inhibitors (ICIs) has improved the clinical outcomes for many people with cancer, immune-related adverse effects can involve various organs, including the pancreas.[68] This class of drugs include cytotoxic T cell–associated protein 4 inhibitors, programmed cell death protein-1 inhibitors, and programmed death-ligand 1 inhibitors. ICI-associated diabetes mellitus reportedly occurs in 0.2% to 1.27% of people treated with these medications following a median duration of therapy of approximately 4 months.[68,69] The condition is characterized by pancreatic atrophy, and the associated hyperglycemia is irreversible, necessitating lifelong insulin therapy. Presentation is typically fulminant, often with diabetic ketoacidosis. Those who have positive GAD65 antibodies prior to therapy and those treated with combinations of these medications appear to be at greatest risk.[70]

Additional compounds that are cytotoxic to β cells include the rat poison vacor and the antipneumocystis drug pentamidine. The hyperglycemia that results from these agents is usually not reversible. Thiazide diuretics can inhibit insulin secretion by causing hypokalemia, and this effect may be picked up on an oral glucose tolerance test as early as 4 weeks following the initiation of therapy. However, these agents do not induce diabetes mellitus in the absence of underlying susceptibility.[71] Glucocorticoids and nicotinic acid cause hyperglycemia by impairing insulin action. Glucocorticoid excess, whether endogenous or exogenous, is also independently associated with many so-called secondary complications of diabetes such as atherosclerosis and cardiovascular disease.[72] "New-onset diabetes after transplantation" is a term used to describe individuals who develop diabetes after transplant and excludes posttransplant hyperglycemia that resolves by the time of discharge from hospital.[27] While this cohort of patients have many risk factors for diabetes development (including severe physiological stress), it is believed that immunosuppressive therapies are a major contributor, particularly in those with preexisting risk factors for type 2 diabetes. Protease inhibitors (PIs) commonly used in the treatment of individuals with human immunodeficiency virus infection can cause hyperglycemia. This effect of PIs probably results from inducing a form of partial lipodystrophy that selects the face and limbs, while causing fat accumulation in the region around the waist.[73] The so-called *atypical* or *second-generation* antipsychotics (for example, olanzapine, clozapine, and quetiapine) are associated with metabolic disorders, including overt diabetes mellitus. The ADA published a consensus statement highlighting this association and identifying the need for clinical research in this area.[74] Although it was initially assumed that the risk of diabetes was directly linked to medication-associated weight gain, there is accumulating evidence that these medications independently decrease insulin sensitivity and insulin secretory capacity.[75] Finally, somatostatin analogs, often used in the treatment of endocrinopathy and neuroendocrine tumors, also inhibit insulin release. This is particularly true for pasireotide, an agent that has a broader selectivity across the somatostatin receptor subtypes. In endocrinopathies associated with insulin resistance such as Cushing disease or acromegaly, use of these agents may result in overt diabetes.[76]

Infections

Certain viral infections, including rubella[77] and coxsackie B virus,[78] have been associated with diabetes. Some studies suggest that a viral infection can trigger autoimmune destruction of β cells in genetically predisposed individuals, leading to autoimmune type 1 diabetes. During the coronavirus disease 2019 (COVID-19) pandemic, a relationship between COVID-19 and diabetes was noted. Like many viral illnesses, the risk of severe COVID-19 infection is higher in those with preexisting diabetes.[79] However, new-onset diabetes is observed in patients with COVID-19 pneumonia more frequently than among those with non–COVID-19 pneumonia, providing support for a potential diabetogenic effect of COVID-19. Viral infection of pancreatic β cells is one proposed mechanism, with significant work ongoing in this area.[80]

Uncommon Forms of Immune-Mediated Diabetes

The stiff-person syndrome is a rare neurologic syndrome characterized by spasticity of the axial muscles. It is associated with very high titers of anti-GAD antibodies, and up to one third of patients develop diabetes.[81] Autoantibodies directed against the insulin receptor represent another rare cause of diabetes (referred to as *type B insulin resistance*).[82] These antibodies have the potential to change from being receptor antagonists (causing insulin resistance) to being receptor agonists (leading to potentially life-threatening hypoglycemia). Spontaneous remission of antibody production can occur. The syndrome is typically seen in Black American females in association with other autoimmune diseases (most commonly systemic lupus erythematosus).

Other Genetic Syndromes Sometimes Associated With Diabetes

Many of the genetic syndromes listed under H in Table 31.1 are known to be associated with diabetes. Wolfram syndrome, also known as DIDMOAD (reflecting the components of the disorder: **d**iabetes **i**nsipidus, **d**iabetes **m**ellitus, **o**ptic **a**trophy, and **d**eafness), is a rare autosomal recessive disorder caused by mutations in the *WFS1* gene on the short arm of chromosome 4. Polymorphisms in the *WFS1* gene have been linked to an increased risk for type 2 diabetes,[83] providing an example of how the study of rare disorders can improve our understanding of common conditions.

KEY POINTS

- "Other forms of diabetes" is a broad category that includes genetic forms of diabetes, diseases of the exocrine pancreas, diabetes related to endocrinopathies, drug-induced diabetes, and diabetes due to specific infections.

Gestational Diabetes

Gestational diabetes mellitus (GDM) is a common medical complication of pregnancy and is defined as diabetes with onset or first recognition during pregnancy, excluding diabetes that was clearly present prior to gestation. Risk factors for GDM include age (it is more common among older women), ethnicity (higher rates are seen among women from ethnic groups with a high incidence of type 2 diabetes), prepregnancy body mass index (the risk increases with degree of obesity), parity (the risk increases with the number of previous pregnancies), and family history of diabetes. A previous pregnancy that was complicated by GDM or a history of delivery of a macrosomic infant also represents a strong risk factor for future GDM.[84] Dysglycemia during pregnancy is associated with complications for both mother and fetus. Fetal/neonatal complications include large for gestational age birth weight, macrosomia, and neonatal hypoglycemia. Maternal complications include higher rates of cesarean section.[84,85] Appropriate diagnosis and management of gestational diabetes potentially reduces the incidence of these related complications. In the long term, women with GDM are at greater risk of type 2 diabetes, and postpartum testing of glycemia is necessary in all women with a diagnosis of GDM.[86]

Table 31.3 outlines commonly accepted approaches to diagnosing GDM. The traditional two-step approach uses diagnostic cutoffs that are predominantly based on the woman's risk of type 2 diabetes following the pregnancy, and outcomes relating to the index pregnancy were not considered at the time of development. The Hyperglycemia and Adverse Pregnancy Outcome (HAPO) study aimed to clarify the relationship between adverse pregnancy outcomes and maternal glucose levels (below the threshold for overt diabetes).[87] The results from this study suggested that updated threshold values were necessary to develop an "outcomes-based" system for diagnosis of GDM.

TABLE 31.3 Screening for and Diagnosis of Gestational Diabetes Mellitus[*]

One-step strategy:

In women not previously diagnosed with overt diabetes, perform a 75-g OGTT (with measurement of plasma glucose fasting and at 1- and 2-hours post–glucose load) at 24 to 28 weeks' gestation when the patient is fasting.

The diagnosis of gestational diabetes mellitus is made when any of the following plasma glucose values are met or exceeded:

Fasting: 92 mg/dL (5.1 mmol/L)
1-hour: 180 mg/dL (10.0 mmol/L)
2-hour: 153 mg/dL (8.5 mmol/L)

Two-step strategy:

Step 1: Perform a 50-g glucose challenge test (nonfasting), with plasma glucose measurement at 1 hour, at 24–28 weeks of gestation in women not previously diagnosed with diabetes.

If the plasma glucose level measured 1 h after the load is ≥130, 135, or 140 mg/dL (7.2, 7.5, or 7.8 mmol/L, respectively)[†], proceed to a 100-g OGTT.

Step 2: A 100-g OGTT should be performed when the patient is fasting.

The diagnosis of GDM is made when at least two of the following four plasma glucose levels are met or exceeded:

Fasting: 95 mg/dL (5.3 mmol/L)
1-hour: 180 mg/dL (10.0 mmol/L)
2-hour: 155 mg/dL (8.6 mmol/L)
3-hour: 140 mg/dL (7.8 mmol/L)

OGTT, Oral glucose tolerance test; *GDM,* gestational diabetes mellitus.Diagnosis based on International Association of Diabetes and Pregnancy Study Groups recommendations and endorsed by the American Diabetes Association.

[*] There is no consensus regarding universal screening versus screening in "at-risk" individuals.

[†] Each of these thresholds may be used for the glucose challenge test. The choice is based upon the trade-off between sensitivity and specificity, and individual clinical practices vary in their approach.

(From International Association of Diabetes and Pregnancy Study Groups Consensus Panel. International Association of Diabetes and Pregnancy Study Groups Recommendations on the Diagnosis and Classification of Hyperglycemia in Pregnancy, *Diabetes Care.* 2010;33:676–682; and American Diabetes Association: Diagnosis and classification of diabetes mellitus. *Diabetes Care.* 2021;44:S15–S33).

Consequently, the International Association of Diabetes and Pregnancy Study Groups (IADPSG) published a consensus statement that sets out updated recommendations for the diagnosis of GDM using the 75-g oral glucose tolerance test (OGTT), performed between 24 and 28 weeks (Table 31.3).[86] The diagnostic cutoffs were chosen based on an adjusted odds ratio of 1.75 for three neonatal outcome variables. These variables had a strong, predominantly linear association with maternal glucose and included birth weight greater than the ninetieth percentile, percent body fat greater than the ninetieth percentile, and cord C-peptide greater than the ninetieth centile.

Worldwide, uptake of the IADPSG guidelines is variable. For example, the International Federation of Gynecology and Obstetrics and the WHO have endorsed the IADPSG criteria,[88,89] and the ADA also recommends these criteria but acknowledges that a two-step strategy can be used.[27] In other jurisdictions such as the United Kingdom, guidelines reflect an adaptation of the IADPSG guidelines based on local prevalence and cost analyses.[90] The prevalence of gestational diabetes increases in parallel with the prevalence of type 2 diabetes in a population. Previous data from a large US healthcare organization described a prevalence of 7.4 cases per 100 pregnancies.[91] Using diagnostic thresholds as set out by the IADPSG, the prevalence of GDM is far higher than that found using a two-step approach. For example, the average prevalence for all HAPO study participants was 17.8%, but this varied from 9.3% at an Israeli center to 25.5% at a US center.[92] Concerns have been raised that the IADPSG criteria impose a diagnosis of GDM on many women who have very modest dysglycemia, without a clear treatment benefit. A recent pragmatic randomized controlled trial supports this argument and reported that, despite more diagnosis of GDM with the IADPSG criteria versus a two-step approach (16.5% vs. 8.5%), there was no significant between-group differences in the risk of primary outcomes relating to pregnancy complications.[93] These observations have led to the suggestion that adoption of diagnostic criteria defining GDM should be based on response to treatment at different diagnostic thresholds of maternal glucose.[94] This would require a randomized controlled trial that would be challenging to design and execute.

Screening for GDM presents a further challenge, and currently there is no consensus on who should be screened.[86,95] In some countries (e.g., the United States), universal screening is undertaken routinely, and this is the recommendation of the IADPSG.[86] However, in other regions (e.g., parts of Europe), only women who are believed to be at high risk are screened.[90] Timing of GDM screening and diagnosis is another area of controversy. The majority of guidelines recommend screening at 24 to 28 weeks' gestation, which coincides with a sharp increase in insulin resistance and risk of hyperglycemia.[27,84] However, the rising tide of obesity and type 2 diabetes in pregnancy requires screening for undiagnosed diabetes as near to conception as possible. Screening for undiagnosed, pregestational diabetes in early pregnancy also identifies women with hyperglycemia less than overt diabetes, but at increased risk of adverse outcomes. There is no agreed approach to diagnosis and management of these women, and while some institutions apply standard GDM criteria to at-risk women in early pregnancy, this practice is not evidence-based. It is hoped that an ongoing randomized controlled trial will clarify if diagnosis and treatment of GDM earlier in pregnancy will result in improved outcomes.

KEY POINTS

- Gestational diabetes mellitus (GDM) is associated with an increased risk of pregnancy complications. While the associated hyperglycemia typically resolves postpartum, women with GDM have a lifelong increased risk of type 2 diabetes.

DIAGNOSIS

Diagnostic Criteria

The modern-day classification of diabetes is based on clinical presentation combined with (in some cases) genetic and autoantibody testing. The diagnosis of diabetes is based on measurement of glucose and/or glycated hemoglobin (HbA_{1c}). A historical perspective is necessary to understand how we got to this point. The Expert Committee of the ADA, in their 1997 report, recommended changes in the diagnostic criteria used for diabetes, in addition to recommending changes in the classification system.[7] These recommendations were subsequently endorsed by the WHO[8] (Table 31.4). Major changes included a reduction in the fasting plasma glucose cut point used to diagnose diabetes from 140 mg/dL to 126 mg/dL and a recommendation to use fasting plasma glucose rather than an OGTT for diagnosis. The ability to use casual (i.e., random) plasma glucose levels in patients with hyperglycemic symptoms was retained, as was the requirement that, in asymptomatic individuals, a diagnosis should be based on testing carried out on more than one occasion. The ADA report based its criteria on use of the fasting plasma glucose level, and the WHO report included equivalent cut points for whole-blood venous and capillary glucose.[8] The

TABLE 31.4 Diagnostic Thresholds for Diabetes and Lesser Degrees of Impaired Glucose Regulation*

Category	Fasting Plasma Glucose	2-Hour Plasma Glucose	HbA$_{1c}$¶
Normal	<100 mg/dL (<5.6 mmol/L)	<140 mg/dL (<7.8 mmol/L)	≤5.7%
IFG	100–125 mg/dL* (5.6–6.9 mmol/L)	—	❖
IGT	—	140–199 mg/dL* (7.8–11.0 mmol/L)	
Diabetes	≥126 mg/dL† (≥7.0 mmol/L)	≥200 mg/dL (≥11.1 mmol/L)	≥6.5%

IFG, Impaired fasting glucose; *IGT* impaired glucose tolerance; HbA$_{1c}$, glycated hemoglobin.

*When both tests are performed, IFG or IGT should be diagnosed only if diabetes is not diagnosed by the other test.

†A diagnosis of diabetes needs to be confirmed on a separate day.

¶The test should be performed in a laboratory using a method that is National Glycohemoglobin Standardization Program (or equivalent) certified and standardized to the Diabetes Control and Complications Trial assay.

❖The American Diabetes Association recommends a range of 5.7%–6.4% as identifying individuals with prediabetes. The use of HbA$_{1c}$ for the diagnosis of prediabetes has not been endorsed by the World Health Organization.

Expert Committee of the ADA published two further reports in 2003 and 2009.[96,97] While recommendations regarding diagnostic criteria for diabetes on the basis of fasting glucose, OGTT, and random glucose have remained unchanged, the 2009 report also added recommendations for use of HbA$_{1c}$ in the diagnosis of diabetes mellitus (see Table 31.4). These updated recommendations for HbA$_{1c}$ have subsequently been included in ADA Clinical Practice Recommendations.[9]

In the 1997 report, the ADA also introduced a new system for classifying the intermediate zone between normal glucose tolerance and overt diabetes.[7] A new category called *impaired fasting glucose* (IFG) was introduced, along with the preexisting category of impaired glucose tolerance (IGT). The presence of one or both of these conditions is often referred to as *prediabetes.*

While threshold values for the diagnosis of diabetes were originally formulated based on the risk for developing retinopathy, the basis for the "diagnosis" of these intermediate categories of hyperglycemia is the risk for developing overt diabetes, hence the terminology "Categories of Increased Risk for Diabetes."[97] The ADA diagnosis of prediabetes uses threshold values of fasting glucose (IFG: 100–125 mg/dL) or 2-hour glucose following a 75-g glucose load (IGT: 140–199 mg/dL).[27] However, there is no overall consensus between the ADA and the WHO for threshold values of fasting glucose, with the latter using an IFG cutoff of 110 mg/dL.[8] The ADA recommends a HbA$_{1c}$ range of 5.7% to 6.4% as identifying individuals with prediabetes.[9] The use of HbA$_{1c}$ for the diagnosis of prediabetes has not been endorsed by the WHO. The main questions of clinical relevance are: (1) what constitutes diabetes? and (2) what constitutes "normal"? We will address both questions now.

What Level of Fasting Plasma Glucose Constitutes Diabetes?

The development of microvascular changes, particularly in the retina, is one of the hallmarks of diabetes mellitus. Because these complications can take many years to develop, it is not possible to use their presence to diagnose the condition. Instead, the level of plasma glucose that confers a risk for occurrence of these changes is used for diagnostic purposes. At the time the 1997 report was written, the best estimate of this level was fasting plasma glucose of 126 mg/dL. This value was based on data from three epidemiologic studies involving Pima Indians, Egyptians, and a US national sample.[7] In all three studies, there appeared to be a threshold of risk (i.e., a level below which the risk for retinopathy was negligible, and above which the risk rose steeply). In the 2003 report of the expert committee, reference was made to a separate analysis of Pima Indian data, suggesting that the threshold at which retinopathy risk increased may be lower than that previously reported.[98] However, the presence of a threshold was not disputed, and the 126 mg/dL cut point for diagnosis remained in place. An analysis of data from two cross-sectional Australian cohort studies and one longitudinal US cohort study has raised doubt about the presence of a retinopathy threshold (Fig. 31.2).[99] All three studies used multiple-field digital retinal photography to identify retinopathy, a more sophisticated method than that used in earlier studies that informed the ADA expert committee decision. The risk for retinopathy in all three studies appeared to be continuous across the entire range of plasma glucose, with up to 10% of individuals demonstrating some degree of retinopathy at levels of fasting plasma glucose well within the range considered normal. These data are consistent with an earlier report from the Diabetes Prevention Program, which also identified retinopathy in individuals with IGT.[100] Taken together, these data suggest that current diagnostic criteria may need further revision. Nonetheless, the current threshold values for glucose in the diagnosis of diabetes have remained unchanged in the most recent recommendations.[8,97]

The most significant new recommendation from the 2009 Expert Committee of the ADA was the inclusion of an HbA$_{1c}$ value of greater than or equal to 6.5% as a criterion for the diagnosis of diabetes.[97] The measurement of HbA$_{1c}$ has been the mainstay of the assessment of glycemic control in clinical practice for many years. However, because of poor standardization of the assay in the past, HbA$_{1c}$ results could not previously be compared across populations. Standardization of the HbA$_{1c}$ assay has been completed in the United States. A further complication of the use of HbA$_{1c}$ in the diagnosis of diabetes is the recommendation by the International Federation of Clinical Chemists that the units used for reporting results be changed from percentage (as used in Diabetes Control and Complications Trial [DCCT]-aligned assays in the United States) to millimoles per mole (mmol/mol). This recommendation has been adopted by many (but not all) European countries. The diagnostic value of greater than or equal to 6.5% (for DCCT-aligned assays) was chosen based on its association with the inflection point for retinopathy, upon which the fasting and 2-hour glucose values have been chosen. HbA$_{1c}$ offers a useful so-called "chronic measurement" upon which to base the diagnosis of diabetes. Measurement does not require the patient to fast or consume a glucose load. However, these benefits must be balanced with consideration of the higher cost of the assay as well as errors associated with high red blood cell turnover states and hemoglobinopathies.

What Level of Fasting Plasma Glucose Constitutes Normality?

Less straightforward than diagnosing overt diabetes has been the characterization of intermediate levels of (what has been termed) *dysglycemia.* At what level does one cross the boundary between normal and abnormal? Glucose is a continuous variable, and therefore choosing a cut point to define the upper limit of normal fasting glucose (and the lower limit of IFG), while informed by clinical risk and observation, is ultimately arbitrary. The Expert Committee, in its 1997 report, chose a value of 110 mg/dL but revised this value to 100 mg/dL in 2003.[96] The updated lower recommendation was based on receiver operator

	≤4.6	4.7–5.4	5.5–6.2	6.3–7.0	7.1–7.8	7.9–8.6	8.7–9.4	9.5–10.2	≥10.3

Figure 31.2 **Prevalence of retinopathy across a wide range of fasting plasma glucose levels in three epidemiologic studies using digital retinal photography to screen the retina.** (Data from Wong TY, Liew G, Tapp RJ, et al. Relation between fasting glucose and retinopathy for diagnosis of diabetes: three population-based cross-sectional studies. *Lancet.* 2008;371:736–743.)

characteristic (ROC) curve analyses of the ability of various baseline levels of fasting plasma glucose to predict future diabetes. ROC curves were derived from cohort studies available to the committee at the time but were not published in the report.

A factor that undoubtedly influenced the committee was a desire to achieve "equivalence" (in terms of predicting future diabetes) between IFG and IGT. The term *equivalence* can be considered as cross-sectional or prospective. In cross-sectional terms, complete equivalence would amount to those patients with IFG also having IGT. This was not the case when the cut point was at 110 mg/dL and still is not the case with the cut point at 100 mg/dL. In fact, it has been suggested that these two states of "prediabetes" may be different biological entities, with altered insulin action and altered β cell function contributing in different ways to their pathogenesis.[101] A lesser degree of cross-sectional equivalence would be a situation in which population prevalences of IFG and IGT are the same. Lowering the cut point to 100 mg/dL did help move things toward equivalence by this definition. In prospective terms, equivalence amounts to an equal ability of these two intermediate states of hyperglycemia to predict future events, such as overt diabetes and cardiovascular disease or mortality. This is the point about which most of the controversy has arisen. A large European epidemiologic consortium published data clearly demonstrating that 2-hour plasma glucose following an OGTT was superior to fasting plasma glucose in predicting future cardiovascular events.[102] Members argued that the OGTT should not be discarded from clinical practice or from epidemiologic research. Many studies have looked at the ability of fasting plasma glucose to predict future diabetes. One of these, the Baltimore Longitudinal Study of Aging (BLSA), followed a cohort of more than 800 subjects with serial OGTTs for up to 20 years.[103] Investigators documented the natural history of progression from normal glucose tolerance to intermediate states of hyperglycemia to overt diabetes. Many subjects reverted to normal from intermediate states of hyperglycemia, but in general, a slow, steady progression to diabetes was seen, with male gender and obesity increasing risk. By altering the threshold that was used to define the lower limit of IFG, BLSA investigators showed that much of the "discrepancy" between rates of progression from IFG versus IGT to overt diabetes was a function of the threshold used rather than of any inherent biological difference between the two states of hyperglycemia. Using the definition of a threshold that we discussed previously, one would expect that the cut point between normal and IFG would be associated with a significant increase in risk. This is not the case. Several investigators have demonstrated that risk for future diabetes and risk for cardiovascular events increase across the continuum of glucose levels from normal through IFG or IGT.[104-107] There does not appear to be a threshold of risk.

Has HbA_{1c} added clarity to this area? The Expert Committee position statement from 2009 declared that HbA_{1c} values of 6.0% to 6.4% represented a category that is described as a "*sub-diabetic, high risk state.*"[97] The ADA, in their 2013 position statement, set out that "*it is reasonable to consider an A_{1c} range between 5.7 and 6.4% as identifying individuals with high risk for future diabetes, to whom the term pre-diabetes may be applied.*"[8,97] These HbA_{1c} thresholds are based upon the future risk of developing diabetes, rather than cardiovascular complications relating to diabetes. The choice of threshold HbA_{1c} values are informed by data from the National Health and Nutrition Examination Surveys (NHANES) as well as the Diabetes Prevention Program (DPP), in which study participants with "prediabetes" had HbA_{1c} values between 5.5% and 6.0% (NHANES) or a mean HbA_{1c} of 5.9% (DPP).[8,100] Several prospective studies were systematically reviewed in a large metaanalysis that included a combined sample of 44,203 individuals. The results of this metaanalysis were published since the last meeting of the Expert Committee, and they have been used in resolving the updated HbA_{1c} threshold values for the identification of a so-called "subdiabetic, high-risk state."[8,108] The HbA_{1c} may actually represent a more powerful predictor of type 2 diabetes than fasting glucose. Ultimately, HbA_{1c}, like fasting glucose, is a continuous variable, and its association with future risk for diabetes or macrovascular or microvascular outcomes is curvilinear. Hence, the choice of the appropriate inflection point at which to "draw a line in the sand" is likely to remain an area of controversy and debate.

KEY POINTS

- Diagnosis of diabetes mellitus is based on fasting glucose, glucose measurements following an oral glucose load, and glycated hemoglobin measurements. Diagnostic values are common to most forms of the disease except for gestational diabetes mellitus.

WHAT'S NEW?

Classification and diagnosis of diabetes has become ever more complicated as our understanding of this heterogeneous set of conditions, underpinned by chronic hyperglycemia, increases. Recently, attempts were made to use clustering methods to create a data-driven classification for patients with diabetes, using six parameters that could be measured in a single clinic visit, including: age at diagnosis, body mass index, glutamate decarboxylase antibodies, HbA_{1c}, homeostatic model assessment 2 (HOMA2)-B (to assess β cell function), and HOMA2-insulin resistance (to assess insulin sensitivity).[109] The study, based in Sweden, identified five replicable clusters of patients with diabetes that had significantly different patient characteristics and risk of complications. Although it was hoped that this would represent a significant step towards precision medicine in diabetes, a validation study did not reveal sufficient predictive accuracy or cluster stability to consider implementation in practice.[110] For the moment, therefore, the appropriate diagnosis, classification, and management of diabetes, while guided by various position statements, require clinical acumen. This is even truer considering the gray area that represents so-called *prediabetes,* a categorization applicable principally to individuals at risk for type 2 diabetes. It remains most sensible to address the diagnosis of prediabetes by taking a holistic approach and considering body mass index, lipid profile, and blood pressure, as well as various glycemic thresholds. In light of the global obesity epidemic, perhaps we should be more liberal with our advice (and interventions) regarding healthy lifestyle, rather than waiting for members of the population to cross arbitrary thresholds.

DEFINITION

Autoimmune type 1 (insulin-dependent) diabetes (T1D) is associated with several immune abnormalities. This form, previously called "juvenile-onset diabetes" or "insulin-dependent diabetes," accounts for 5% to 10% of diabetes patients. T1D results from a selective destruction of the pancreatic β cells, eventually leading to an absolute lack of insulin and hyperglycemia. T1D is frequently recognized because of symptoms of polyuria, polydipsia, weight loss, and fatigue. These symptoms develop due to the failing β cell function, gradually worsening over time. Diabetes as such is diagnosed based on plasma glucose criteria, by fasting plasma glucose value, random plasma glucose, or the 2-hour plasma glucose value during a 75-g oral glucose tolerance test (OGTT)[1] concurrent with diabetes symptoms. In the absence of unequivocal hyperglycemia or diabetes symptoms, the elevated glucose values need to be repeated for a diagnosis to be made. Typically, when age at onset of diabetes is young, classification of the disease is uncomplicated.[1] T1D may occur globally and at any age.[2] The fact that T1D in adults may fulfill clinical criteria of type 2 diabetes (T2D) demonstrates the limitation of a disease classification based on clinical symptoms rather than on etiology and pathogenesis. Pancreatic islet autoantibodies that both predict and differentiate T1D from other forms of diabetes are included among the diagnostic criteria for T1D.[1]

The T1D autoimmune biomarkers include GAD65 autoantibody (GADA), insulin autoantibody (IAA), islet antigen-2 autoantibody (IA-2A and IA-2βA), and zinc transporter 8 autoantibody (ZnT8A).[3,4] These autoantibodies are either endpoints in ongoing primary prevention studies[5] or inclusion criteria in secondary prevention studies aimed at preventing the onset of diabetes.[6] Autoantibody biomarkers are additionally used to stage T1D (Fig. 32.1). Stage 1 diabetes is defined by the presence of two or more autoantibodies but normoglycemia and an absence of symptoms. Stage 2 is characterized by two or more biomarkers with dysglycemia but no symptoms. Stage 3 is diagnosed diabetes. Staging T1D should prove useful to improve the design of both primary and secondary prevention trials.

Classification of diabetes has become complicated during the current obesity epidemic among the young, making differentiation between T1D and T2D more difficult.[7,8] It has been known for decades that diabetes mellitus can be diagnosed at different degrees of severity, and that the diagnostic criteria used to differentiate between T1D (insulin-dependent) and T2D (non–insulin-dependent) are important for understanding the etiology and pathogenesis of these two disease entities. The etiology of T1D has not been clarified, while the pathogenesis is somewhat better understood (Fig. 32.1). Using molecular genetics, it has also been possible to define a number of monogenic forms of diabetes[9,10] involving mutations in the genes for insulin, the insulin receptor, glucokinase (maturity-onset diabetes in the young; MODY-2), HNF-4α (MODY-1), and HNF-1a (MODY-3).[9] The clarification of the etiology of these diabetes phenotypes is a major advancement that has increased the diagnostic precision of diabetes syndromes. Our understanding of the more complex and multifactorial T1D syndrome has also seen significant advances.

EPIDEMIOLOGY

Prevalence

The prevalence of T1D is low compared with that of T2D. Among individuals aged 30 years or younger, the prevalence of T1D does not usually exceed approximately 0.3%, compared with prevalence rates for T2D of 4.2% worldwide and nearly 25% in certain high-risk

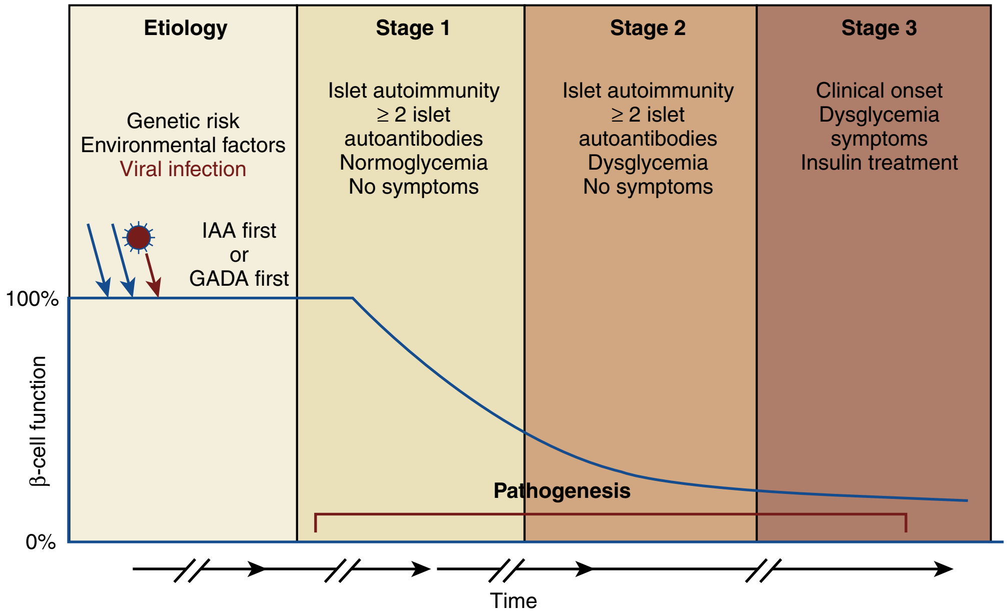

Fig. 32.1 Etiology and pathogenesis of autoimmune type 1 diabetes (T1D). The etiology is genetic and environmental, in yet unknown combinations. Biomarkers of two different endotypes are autoantibodies appearing either against insulin autoantibody (IAA) or glutamic acid decarboxylase autoantibody (GADA) first. The pathogenesis is initiated by islet autoimmunity to two or more autoantibodies (IAA, GADA, or autoantibodies against islet antigen-2, or Zn transporter 8) but normoglycemia and no symptoms (stage 1). Two or more autoantibodies remain, but dysglycemia develops (stage 2). The clinical onset is defined by dysglycemia (hyperglycemia), diabetes symptoms, and insulin requirement (stage 3). The loss of functional β cell mass is illustrated as a continuous variable, but the rate of loss varies between individuals dependent on the age at the first appearing islet autoantibody in combination with genetic and environmental (e.g., additional viral infections) factors. Dependent on the endotype of first appearing autoantibody, time represent months to years.

populations.[11] While current attention is directed toward the trends of the "epidemic" or "tsunami" of T2D, recent data suggest that there is a parallel rise in the prevalence of both T1D and T2D.[11] Both geographic and ethnic variations are seen in the prevalence rates. The International Diabetes Federation estimated that in 2015 there were 415 million (uncertainty interval: 340–536 million) people with diabetes aged 20 to 79 years.[11] It has been pointed out that the results of prevalence studies should be viewed with caution. Different age groups were studied, and, although geographical variation may be related to variations in genetic predisposition, environmental risk factors, or both, it may also be due to some research methodology problems.[11] In addition, it is unclear whether recently observed increases in incidence rates worldwide and in specific regions reflect a change in the age at onset of diabetes or a true increase in prevalence of T1D.[2,8,12]

Incidence

The incidence rate is the frequency with which new patients with T1D are detected during a defined period. The rate is expressed as an annual number of patients per 100,000 age-corrected individuals. A determination of incidence rate therefore requires a precise knowledge of the total number of individuals in each age group and the number of new patients diagnosed during one year in the particular area. Determinations of secular trends constitute an important part of population-based epidemiologic studies. However, such analyses are rare because they require careful follow-up investigations for several subsequent years.

Globally, the current rise in incidence rates by 3% (2%–5%) is expected to be 40% higher in 2020 compared with figures from 1998[12,13] (Fig. 32.2). Currently it is estimated that more than 70,000 new patients are diagnosed each year worldwide.[12-14] There are suggestions that the increasing incidence rates and changing trends are seen not only in populations with high incidence but also in populations with previously lower incidence rates.[12,14] Over the last three decades, T1D has shown temporal trends in most of the regions of the world except Central America and the West Indies, while European data showed that the main recent rise in incidence rates is in Central-Eastern countries.[2,11] EURODIAB[15] and DiaMond[16] have attempted to better define the incidence rates in various populations by using prospective, population-based, geographically defined registries. Overall, the average annual incidence rate varies widely, from 0.1 per 100,000 children in parts of Asia and South America to 64.2 per 100,000 in Finland.[11,16] Pooled data from all sites in the EURODIAB study demonstrated an annual rate of increase in incidence of 3.4%, with more rapid rates of increase occurring in certain regions.[15] Approximately 1% of all children born in Scandinavian countries will manifest T1D during their lifetimes. The causes of the rapid rise in incidence are not understood, and further studies are needed to define to what extent the rise may be due to environmental factors, genetic admixture, or both.

Geographical Distribution

T1D can occur in any region of the world, and recently it was observed that the incidence is increasing in countries with both high and low incidence rates; in the latter group, the rise is steeper.[11] The annual incidence of T1D is higher in northern Europe than in the Mediterranean area, with the exception of Sardinia (Fig. 32.2). Furthermore, the incidence in Iceland is lower than that in Sweden or Finland.[17] Surprisingly, the T1D incidence rate in Estonia is approximately 25% of the rate in Finland, in spite of their close geographic proximity.[17,18] The incidence

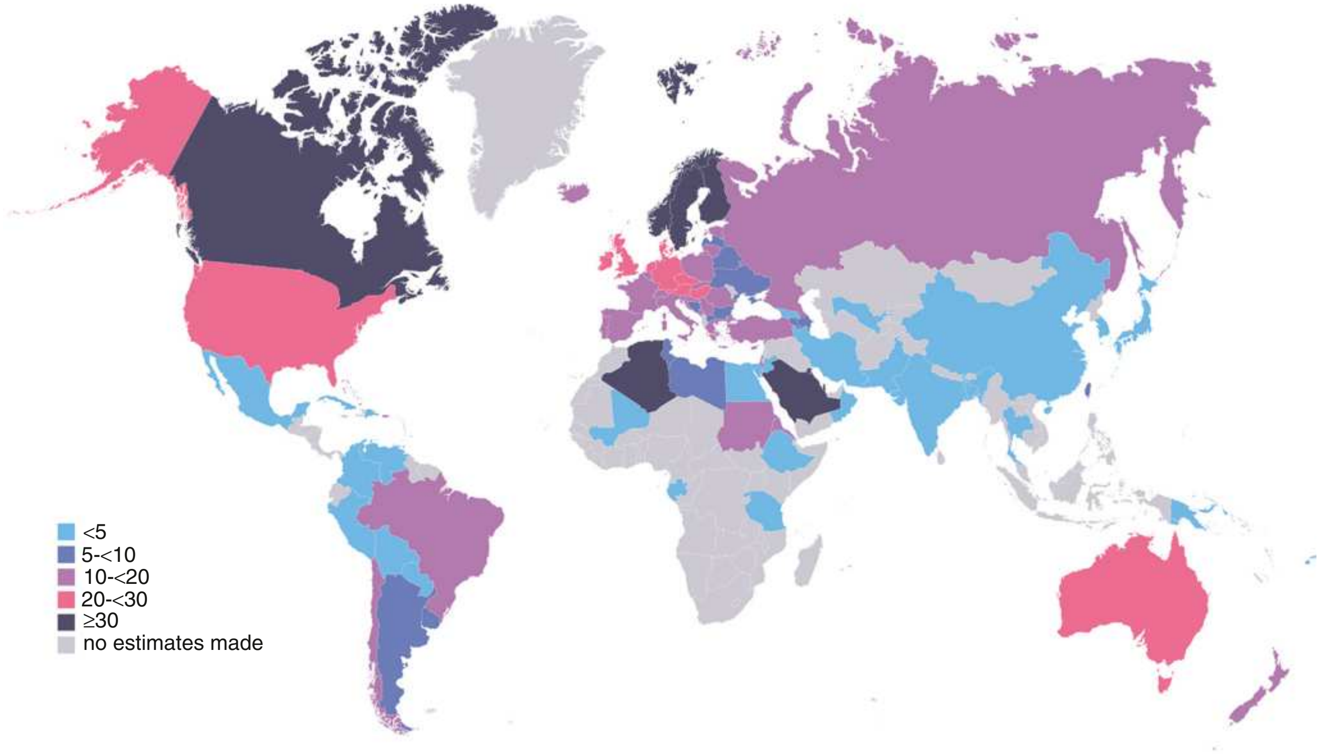

Fig. 32.2 Incidence rates standardized for age and sex per 100,000 population per year of type 1 diabetes in children and adolescents aged 0–14 years. (From International Diabetes Federation. IDF Diabetes Atlas, 10th edn. Brussels, Belgium: International Diabetes Federation, 2021. http://www.diabetesatlas.org.)

rates within countries also show stable differences. The eastern and southern parts of Finland,[19] as well as the central and southern parts of Sweden,[17] have had higher incidence rates than the northern parts of those countries.

The cause of geographic variation remains unknown, but it has been speculated to be related to genetic factors primarily associated with different human leukocyte antigen (HLA) DR or DQ genotypes of the major histocompatibility complex (MHC) on chromosome 6. HLA class II molecules from the DQ and DR loci that are necessary (but not sufficient) for disease vary greatly between countries, and therefore affect disease incidence.[20] In addition, environmental factors are important in understanding both the etiology and the pathogenesis of T1D and may also help to explain differences in geographic distribution. This is supported by the observation that monozygotic twins show less than 20% to 30% concordance rates for T1D.[21]

In the *European region,* incidence rates show correlation with the frequency of HLA susceptibility genes in the general population. In this region, there is also wide variation in incidence rates, ranging from 6 to 62 cases/100,000/year among children 0 to 14 years of age, with higher rates observed in Scandinavian countries, especially Finland and Sweden. In countries with populations of European origins, there is less variation: *Canada* reports 21/100,000/year, the *United States* 16/100,000/year, and *New Zealand and Australia* have incidence rates ranging from 16 to 20 cases/100,000/year. In the *Middle East* and *North Africa,* few reliable data are available. The incidence rates range from 1/100,000/year in Pakistan to 8 to 12/100,000/year in Egypt, Sudan, and Libya; however, reports from Kuwait showed a rise in incidence rates from incidence rose from 17.7 in 1992 to 1994 to 40.9 per 100,000 per year in 2011 to 2013.[22,23] There are few published data from the *Southeast Asian region,* and data from the *African region* are mostly lacking. In *South* and *Central America,* the incidence rates are low, except for Argentina and Uruguay, with 6.8 cases/100,000/year and 8.3 cases/100,000/year, respectively. The *Western Pacific* countries have low incidence rates, especially China, which has one of the lowest incidence rates worldwide, ranging from 0.1 to 0.6 patients/100,000/year (Fig. 32.2).[11,23]

It has been described that migration of people from relatively low-incidence countries into countries with a “diabetogenic” environment (i.e., with high incidence rates) increases the risk among the migrant groups. Migrants, within a short period of time, assume comparative risks of the native population, and several studies confirm the importance of country of origin in the risk of T1D.[24] Improved epidemiology and better diagnostic criteria to distinguish different forms of diabetes are critical in obtaining reliable incidence rates for various countries and states.

Variation with Age

Epidemiologic studies with rigorous diagnostic criteria suggest that the clinical onset of T1D may occur at any age. The incidence rate varies with both age and gender (Fig. 32.3). The peak for both girls and boys, at age 11 to 14 years, has been discernible in most studies and seems to be present irrespective of the country or area studied. This peak is associated with puberty and the maximal velocity of pubertal growth, and it may be associated with reduced insulin sensitivity due to hormonal factors related to growth.

Previous studies have suggested that the annual rate of increase in incidence is higher in younger age groups, with rates of 6.4% in 0- to 4-year-olds, 3.1% in 5- to 9-year-olds, and 2.4% in 10- to 14-year-olds.[15]

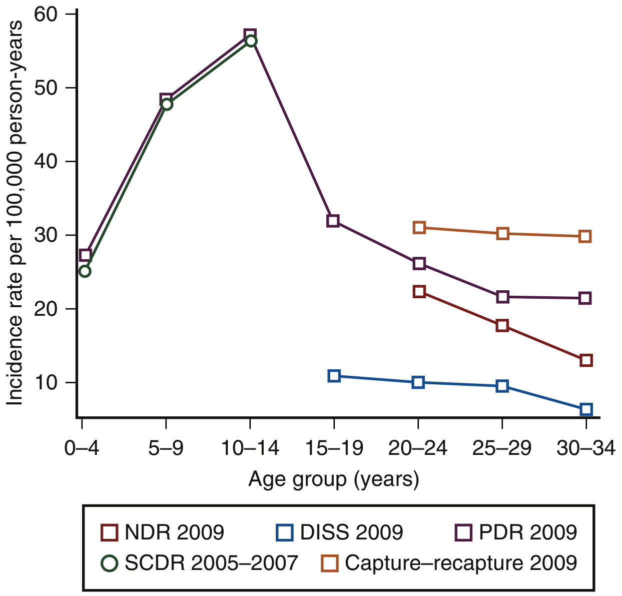

Fig. 32.3 Age-adjusted incidence rates per 100,000 person-years of type 1 diabetes by age group and register. *NDR*, National Diabetes Registry; *DISS*, Diabetes Incidence Study in Sweden; *PDR*, Prescribed Drug Register; *SCDR*, Swedish Childhood Diabetes Register. (Data from Rawshani A, Landin-Olsson M, Svensson AM, et al. The incidence of diabetes among 0-34 year olds in Sweden: new data and better methods. *Diabetologia*. 2014;57:1375–1381. Used with permission.)

In children, minor incidence peaks also occur at 4 to 6 years and 7 to 8 years, which have been associated with preschool or school programs.[15] Recent data suggest that around 50% to 60% of cases of T1D in Western countries occur before 15 years of age, and that more than 90% of childhood and adolescent diabetes is T1D.[12,25] Epidemiologic investigation has indicated that the incidence rate of T1D in patients older than 20 years is lower than that seen in children, except for a possible peak at around 50 to 65 years. In addition to adults having what is considered a more classic T1D clinical characteristics, some adult patients initially classified and treated as having T2D may require insulin after 1 to 5 years of therapy with diet, exercise, or oral hypoglycemic agents. This type of diabetes is referred to as *type 1.5 diabetes, latent autoimmune diabetes in the adult* (LADA), or *slowly progressive insulin-dependent diabetes mellitus.*[26-28] These patients are positive for islet autoantibodies and have lower body mass index and higher frequencies of high-risk HLA genotypes compared with other “type 2” patients. It is speculated that these patients in fact have T1D in addition to genetic factors that may inhibit rapid progression of β cell killing.[29]

Although rare, some forms of diabetes mellitus can occur at birth or during the first months of life. *Neonatal diabetes* (NDM) is diagnosed during the first months of life (up to 6 months) at a rate of 1 in 500,000 live births. It is characterized by insulin-sensitive hyperglycemia. Approximately half of patients with NDM are transient (TNDM), but the remaining progress into a permanent (PNDM) type, with lifelong dependence on exogenous insulin. Clinically the infant presents with polydipsia, polyuria, hyperglycemia, and/or glycosuria, but the condition may progress into ketoacidosis. PNDM usually proceeds after the second year, and differentiation between the two forms can only be done through genetic testing. TNDM occurs at birth up to 3 to 6 months and is correlated with defects in specific genes: ZAC pleomorphic adenoma gene-like 1 (also known as *PLAG1*)/hydatidiform mole-associated and imprinted transcript (*ZAC/HYMAI*), *KCNJ11*, *Kir6.2* gene, hepatocyte nuclear factor 1β (*HNF1β*), or sulfonylurea receptor 1 (*SUR1*).[30,31] PNDM, on the other hand, is related to several gene defects, such as activating mutations in the *KCNJ11/Kir6.2* gene that encodes for the ATP potassium channel (K_{ATP}), mutations in the *ABCC8* gene that encodes SUR1, complete deficiency of the glucokinase *IPF1/PDX1* gene that encodes insulin promoter factor 1, mutations in the *PTF1A* gene that encodes pancreas transcription factor 1A, mutations in the *EIF2AK3* gene encoding protein kinase R (PKR)-like endoplasmic reticulum kinase (PERK),[32] and mutations in the forehead box p3 (*FOXP3*) gene (also known as the *T-cell regulatory gene*).[33]

Variation With Gender

It has been reported that the peak incidence in girls occurs earlier than in boys. If the clinical onset of T1D is linked to pubertal growth, this difference in incidence rate may be explained by the fact that pubertal growth occurs earlier in girls. In children followed from birth due to T1D genetic risk, the male-to-female ratio was 1.4:1.0 before 6 years of age at T1D diagnosis.[34] This ratio was increased (1.7:1.0) among children younger than 18 months of age. Prepubertal boys were found to be taller at the clinical onset of T1D.[35] In addition, newly diagnosed children of both genders showed advanced skeletal maturity. Even if boys tend to show an increased height compared with controls, their growth seems to cease approximately 35 weeks before the clinical onset of T1D.[35] Therefore, it is possible that processes affecting the pancreatic β cell mass and the ability to produce insulin may have profound effects on body growth and function at a young age. Because these processes differ slightly between boys and girls, growth characteristics may offer a simple explanation for the differences seen in incidence rates between the genders.

A study that examined sex differences in T1D incidence before the age of 15 years showed a slight male preponderance in many, but not all, European countries, whereas a female preponderance was found in most African and Asian countries.[36] Interestingly, the male excess was seen in all countries with the highest incidence rates ($>20/10^5$/yr), whereas a female excess was seen in all countries with low incidence rates ($<4.5/10^5$/yr). Studies of older age groups have consistently shown a male preponderance for new patients with T1D, with male/female ratios ranging from 1.3:1 to 2.5:1. One registry of T1D among 15- to 34-year-olds (Fig. 32.3) demonstrated that T1D was 1.5 times more common among men than women.[4,37] Further studies are necessary to document gender-dependent incidence rates and to explain their mechanisms.

Seasonal Variation

T1D shows cyclic, sinusoidal appearance of seasonal variation in date of diagnosis, with a peak during the winter months. This variation is proposed to be related to the timing of occurrences of certain precipitating factors such as viral infection and cold climate.[38] It is of interest that islet cell autoantibodies (ICAs) appearing during the prediabetic state follow similar seasonal variations, being more prevalent in colder months and rare in summer and spring. Additionally, the triggering of β cell autoimmunity appears to have variable trends over subsequent years and does not equally affect genetically susceptible siblings.[24] These observations suggest that triggering of immunologic markers may be related to factors (most likely viruses) that prevail mostly in colder months with variable frequency of occurrence.

KEY POINTS

- The global rise in incidence rates by 3% and is expected to be 40% higher in 2020 compared with 1998. Currently it is estimated that more than 70,000 new patients are diagnosed each year worldwide.

INHERITANCE

The mode of inheritance is complex, and around 80% to 85% of cases of T1D occur sporadically without familial aggregation. Among HLA-identical siblings of T1D-affected patients, approximately 20% eventually manifest the disease. The overall lifetime risk for first-degree relatives has been estimated at approximately 8% for siblings—15 times higher than the general population—and 5% for children of parents with T1D. The risk of T1D among offspring ranges from 2% to 4% if the mother was affected, compared with 6% to 9% if the father was affected, and the risk increases to 30% when both parents are affected.[39,40]

NATURAL HISTORY AND DISEASE STAGING

Early histologic studies of pancreatic tissue of diabetic patients who died shortly after clinical onset revealed that the pancreatic islets were altered by fibrosis, hyalinosis, atrophy, and infiltration of inflammatory cells.[41] The inflammatory lesion of the islets of Langerhans was described as *insulitis,* and quantitative studies of the pancreatic islets showed a specific loss of insulin-producing cells in association with clinical onset of T1D.[41] It was therefore suggested that the pathogenesis of T1D involved autoimmune reactions directed toward the endocrine pancreas. This notion was supported by leukocyte migration inhibition to pancreatic islet antigens.[42] Numerous studies have confirmed the presence of insulitis[43-45]; however, in spite of the assumption that T1D is a T-cell–mediated disease, reproducible and standardized tests of blood T-cell reactivity against islet autoantigens are yet to be established.

Long-sought-for ICAs were described in 1974,[46,47] islet cell surface antibodies (ICSAs) in 1978,[48] and complement-dependent antibody-mediated islet cell cytotoxicity in 1980.[49] The first autoantigen recognized by islet antibodies, an islet protein of 64,000 relative molecular mass (*Mr*), or 64K, was described in 1982.[50] The 64K protein was found to have glutamic acid decarboxylase (GAD) activity,[51] but molecular cloning showed that the human islet GAD was a novel isoform, GAD65.[52] Autoantibodies to insulin were demonstrated in 1983,[53] to islet antigen-2 (IA-2), a tyrosine phosphatase-like protein, in 1994,[54] and to the zinc transporter 8 (ZnT8) in 2007.[55] In contrast to T-cell analyses, GADAs and IA-2As may be determined in standardized assays.[56] Taken together, ample evidence exists that islet cell autoimmunity is of major importance in the etiopathogenesis of T1D. However, these autoantibodies caused a paradigm shift that rewrote the natural history of the disease. It was possible for the first time to ask the when the first of these T1D biomarkers appeared.

Because T1D is detected in the majority of patients after a relatively short period of symptoms, such as excessive thirst, polyuria, and unexplained weight loss, the natural history of the disease has been poorly defined until recently. With the current ability to define individuals at high risk for T1D based on high-risk HLA and autoantibody positivity, our understanding of the prediabetic period is improving. Prospective studies from birth of children with increased risk for T1D (TEDDY, DIPP, DAISY, DiPiS, BABYDIAB, PANDA) have revealed that autoantibodies to GAD65, IA-2, or insulin and decreased ability to release insulin in response to glucose may develop several years before the clinical diagnosis. The sequence of events preceding the diagnosis of overt T1D would include the following: (1) genetic predisposition; (2) overt immunologic abnormality reflected in a first appearing islet autoantibody but with normal glucose levels and no symptoms; (3) development of a second or third islet autoantibody still with normal blood glucose and no symptoms; (4) development of β cell dysfunction and dysglycemia but no symptoms; (5) development of overt hyperglycemia with detectable C-peptide; and (6) the final stage of insulin dependency, with loss of detectable C-peptide. The fact that T1D develops in persons of all ages must be taken into account when studying the natural history in children and adults. Based on the natural history and using islet autoantibodies as biomarkers for islet autoimmunity, type 1 diabetes has been staged as follows: *stage 1*, two or more islet autoantibodies with normoglycemia; *stage 2*, two or more islet autoantibodies with dysglycemia; *stage 3*, diagnosis of diabetes[6] (Fig. 32.1).

KEY POINTS

- Using islet autoantibodies as biomarkers for islet autoimmunity, type 1 diabetes has been classified into the following stages: *stage 1,* two or more islet autoantibodies with normoglycemia; *stage 2,* two or more islet autoantibodies with dysglycemia; *stage 3,* diagnosis of diabetes.

ETIOLOGY

The absence of an unambiguous mode of inheritance, the presence of a period of subclinical islet autoimmunity preceding clinical onset of disease, HLA genes that control the immune response, and age and seasonal variation must be taken into account in attempts to explain the cause of T1D. A defined etiologic factor, endogenous or exogenous, capable of causing T1D remains to be identified. Because evidence exists of genetic heterogeneity in T1D, it is possible that different causative factors are responsible. The approach to dissecting the etiology of T1D has been to identify children at risk at birth and follow them prospectively until the appearance of a first islet autoantibody and subsequent follow-up for a second or third autoantibody until the clinical diagnosis of diabetes. In a first attempt, children born to mothers or fathers with T1D were followed from 9 months of age in BABYDIAB.[57] Subsequently, children born with high-risk HLAs for T1D were followed from 3 months of age in DIPP[58,59] and DAISY.[60,61] While IAA showed an early appearance in BABYDIAB,[57,62] it was not until the DIPP[63] and TEDDY[64,65] studies that two endotypes were discovered.[66] The first was children who develop IAA as the first appearing autoantibody at 1 to 4 years of age (Fig. 32.4A), primarily in HLA DR4-DQ8 children.[66,67] The second was children who developed GADA at 2 to 3 years of age (Fig. 32.4B), primarily in HLA DR3-DQ2 children.[66,67] While the incidence of IAA first decreased with increasing age, the incidence of GADA first remained elevated. Further data suggest that the two endotypes—IAA first and GADA first—may also, prior to seroconversion, be related to reported virus infection,[68] analysis of the virome to indicate enterovirus B prolonged shedding,[69] and metabolomics differentiating the two endotypes.[70,71]

Genetic Etiology

Human Leukocyte Antigen Genes. T1D is both genetically associated with and linked to certain HLA genetic factors of the MHC on chromosome 6. DNA sequence analysis has revealed that more than 90% of all patients in whom T1D onset occurs before age 30 years are positive for the HLA haplotypes *DRB1*04-DQAI*03:01-BI*03:02(DR4-DQ8)*, *DRBI*03-DQA1*05:01-BI*02:01*, or both (Table 32.2). Although some 40% of the background population carry these HLA factors, they represent necessary but insufficient prerequisites for T1D. It has been estimated that HLA contributes approximately 50% of T1D risk among first-degree relatives of T1D patients.[72] Hence, it is not surprising that less than 10% of genetically susceptible subjects

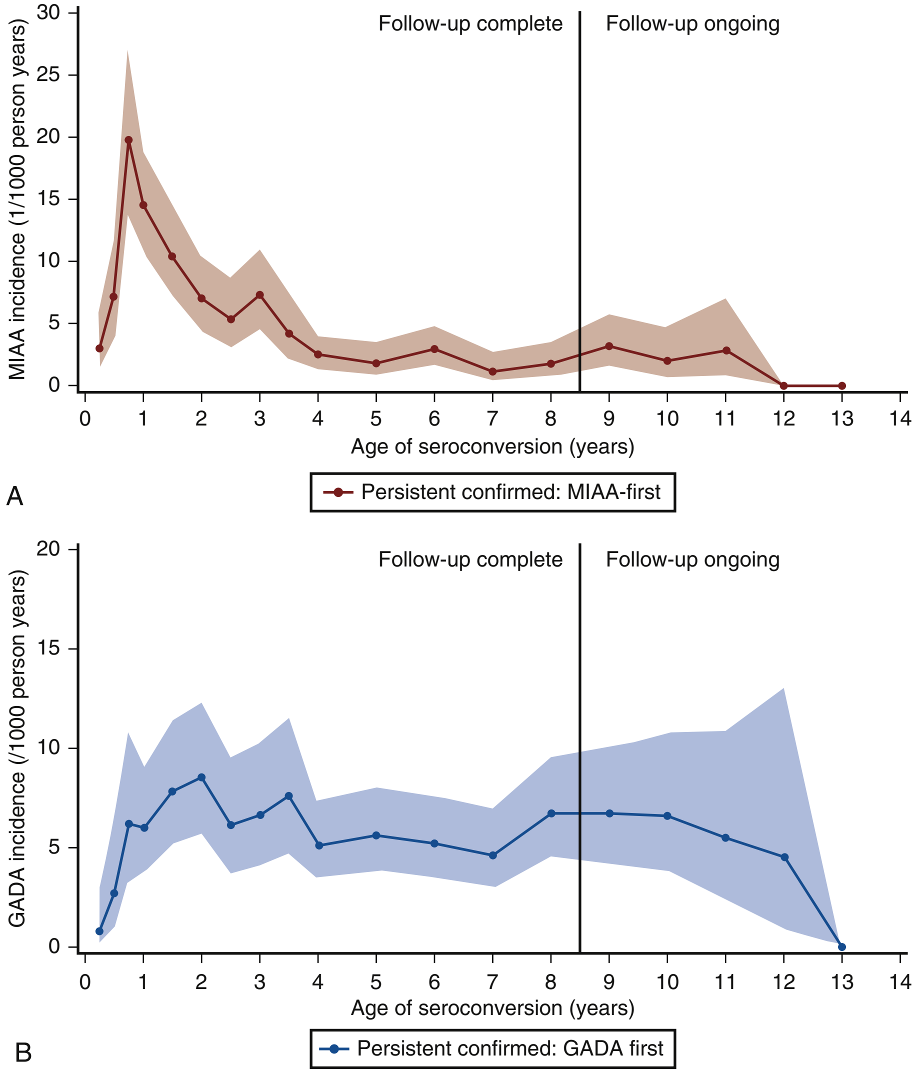

Fig. 32.4 **A,** Incidence rate of insulin autoantibodies (IAA) as the first appearing islet autoantibody in the The Environmental Determinants of Diabetes in the Young (TEDDY) study. **B,** Incidence rate of autoantibodies against glutamic acid decarboxylase (GADA) as the first appearing islet autoantibody in the TEDDY study. The difference in incidence rate suggests that the triggering of islet autoimmunity represents two different endotypes. *MIAA,* Microassay insulin autoantibodies. (Data from the TEDDY study. Used with permission.)

develop the disease. Other genetic factors have indeed been identified, but none has shown a level of importance comparable to that of HLA.[39,73]

The detailed mechanisms by which HLA confers either risk or resistance is not fully understood. The function of these molecules is to display peptide antigens to be recognized by T cell receptors. The disease association may therefore be related either to an inability to induce immunologic tolerance to certain autoantigens or to antigen presentation of an endogenous autoantigen such as enterovirus.[69] In the first case, the subject may be exposed to infectious agents that mimic autoantigens. Reactivity to the infectious agent sets off an immune response that crossreacts with self. In the second case, the immune reaction may result in a direct attack on the individual's own cells.

Non–Human Leukocyte Antigen Genes. The genetics of T1D have been studied extensively, because it represents a paradigm for genetically complex diseases. Genome screens and studies of candidate genes have provided evidence for genetic linkage between T1D and more than 60 polymorphic genetic markers (single nucleotide polymorphisms).[9,72,74] Currently, the genetic markers associated with T1D risk need to be related to possible mechanistic contributions.[72] The clinical diagnosis of T1D is based on specific criteria, not whether IAA or GADA is the first islet autoantibody to appear (as a marker of etiology) or whether a genetic factor representing pathogenesis is present. The latter would raise the question of whether a genetic marker would indicate T1D pathogenesis (stage 1 and 2) or definitive end-stage T1D (Table 32.3). *PTPN22* (chr.1p13), *CTLA-4* (chr.2q33), *IFH1* (chr.2q24), *IL2* (chr.4q27), *ITPR3* (chr.6p21), *IL2RA* (chr.10p15), *INS-VNTR* (chr.11p15), *TH* (chr.11p15), *ERBB3* (chr.12p13), *C12orf30* (chr.12q24), *CLEC16A/KIAA0350* (chr.16p13), and *PTPN2* (chr.18p11), as well as *BACH2* (chr.6q15) and *UBASH3A* (chr.21q22), are all associated with increased T1D risk (Table 32.3). Taken together, these and other genetic factors have limited effects on the relative risk of T1D.

The genetic factors need to be analyzed in relation to the etiology and pathogenesis. The etiology is reflected by the first appearing islet autoantibody. IAA-first was associated with the *INS* gene and GADA-first with *BACH2-T* allele.[67,75,76] Once two or more islet autoantibodies have

*The five most susceptible (S).

†The four most protective (P).

The commonest high-risk haplotype is: HLA DR4-DQ8 (DQBI*03:02-A1*03:01).

The commonest moderate-risk haplotype is: HLA DR3-DQ2 (DQB1*02:01-A1*05:01).

developed without (stage 1) or with (stage 2) dysglycemia, other genetic factors contribute to the pathogenesis. It needs to be determined if these genetic factors contribute to the clinical onset of T1D (stage 3) by being protective or if they have an additive or potentiating effect on the risk provided by HLA. It is noted that most of the genetic factors linked to T1D risk are involved in the function of the immune system.

Environmental Etiology

Viral Etiology. There are numerous reports of individual patients in whom T1D onset followed an acute viral infection, borne out by subsequent animal studies in which viruses have been shown to have diabetogenic activity.[77] The first case linking T1D to an acute viral infection was reported in the late nineteenth century; the onset of T1D appeared to be precipitated by a mumps infection in a child.[78] Many similar reports have followed since, and, taken together, suggest a relation between the clinical onset of T1D, and several viruses, including rubella virus, mumps virus, coxsackie B virus, rotavirus, cytomegalovirus, and Epstein–Barr virus, have been implicated.[77] The true relation between these viral diseases and the clinical onset of T1D remains conjectural (Table 32.3).

Viruses are thought to increase the risk of T1D through different proposed mechanisms. Whereas some viruses induce a rapid and direct effects, causing β cell destruction and subsequent insulin deficiency, other viruses induce slower, longstanding effects through activation of autoreactive T cells (Table 32.4). Viruses may also inhibit insulin production by inducing interferons and HLA antigen expression, or they may mimic β cell autoantigens.[77,79]

Maternal enteroviral infection during pregnancy also appears to be a risk factor for childhood T1D. It is therefore possible that gestational infections by many types of viruses affect the maturation of the immune system, causing certain children to be more predisposed to autoimmunity, thereby increasing the risk for T1D. Prior exposure to measles, mumps, and rubella, but not vaccination, decreased the prevalence of pancreatic and thyroid autoantibodies and also the prevalence of appearance of IAA first.[69,80]

Coxsackie B virus was isolated from the pancreas of a child who died at presentation with T1D. It was propagated in *in vitro* cultures of endocrine pancreatic cells and was shown to have diabetic activity in certain mouse strains. Two important hypotheses follow from these experiments. One hypothesis is that the coxsackie B virus induces β cell neoantigens, which initiate an (auto)immune reaction. This hypothesis can be tested by analyzing the appearance of such neoantigens. The neoantigen may initiate a devastating reaction if its structure mimics a self protein. Another hypothesis is that coxsackie B virus replication in β cells results in β cell necrosis and the formation of antibodies against β cell constituents or "hidden antigens" not normally surveyed by the immune system. An autoimmune reaction is initiated, reflected by IAA as the first appearing autoantibody. It was reported that GADA first may appear in relation to a gastrointestinal infection, possibly by mastadenovirus, also related to prolonged shedding.[69] The etiology of T1D may therefore be related to an early initiation where infection by virus is involved but may not be sufficient, as indicated by the possible contribution of gestational infections[68] or maternal life events during pregnancy.[75]

Psychosocial Factors. Case control studies have reported that negative life events occurring during the first 2 years of life, difficult adaptation, or child behavioral deviances may increase the risk of T1D.[81] It has also been reported that psychological stress, measured as psychosocial strain during pregnancy, seems to be involved in the induction or progression of β cell–related autoimmunity in cord blood and during the first year of life.[82] Additionally, high parenting stress, experiences of serious life events, foreign origin of the mother, and low socioeconomic status were all associated with β cell–related autoimmunity in young children.[82-84] It was hypothesized that the parent–infant relationship may be a "psychobiological regulator," and that early disruption of this relationship may cause stress and affect the hypothalamic-pituitary-adrenal axis (Table 32.4). Such changes may affect the immature autonomic nervous system of the child and subsequently impair the regulation of autoimmunity.[75]

Maternal Factors. Several maternal factors were reported to increase the risk of T1D in children. Higher maternal age (and to a lesser extent,

paternal age) at the time of delivery increased the risk of T1D in the offspring. On the other hand, birth order seems to have positive association with the risk of T1D, as the first child carries the highest risk, and this risk declines by 15% with each new child. Exposure of the mother to enteroviral infection, colder season of delivery, ABO blood group incompatibility, maternal islet autoantibodies, or eclampsia all increased the risk of T1D.[85,86] An analysis of nondiabetic mothers with islet autoantibodies at delivery indicated that an association between HLA and islet autoimmunity may depend on enterovirus exposure during pregnancy.[87 88] Cord blood from children who developed islet autoimmunity or T1D before 8 years of age showed changes in phospholipids that would mark their risk for T1D.[89,90] These and other investigations in humans underscore the importance of clarifying whether transmission of maternal autoimmunity, including placental transfer of autoantibodies, affects the incidence of T1D in susceptible offspring.

Dietary Factors. The dietary hypothesis is based on earlier observations that breastfed children have a lesser risk of T1D. It was also noted that early exposure of infants younger than 6 months to cow's milk proteins may double the T1D risk, particularly in HLA high-risk children. Other studies have described an association between islet autoimmunity and shorter duration of breastfeeding, as well as early exposure of infants to bovine protein (Table 32.4). The use of a hydrolyzed formula, when compared with a conventional formula, did not reduce the incidence of diabetes-associated autoantibodies after 7 years in the TRIGR study.[91] Similarly, the EURODIAB Substudy-2 Group suggested that rapid growth, rather than cow's milk or early introduction of solid food, would explain the increased incidence rate of T1D.[38] Vitamin D or n-3 fatty acid supplementation during pregnancy showed no benefit regarding islet autoantibody risk.[92] Early probiotic supplementation may reduce the risk of islet autoimmunity in children at the highest genetic risk of T1D,[93] but not the intake of dietary soluble fiber in early life.[94] Later introduction of gluten was associated with increased risk of any islet autoantibody.[95]

Toxic Substances. Alloxan and streptozotocin are widely used to induce β cell destruction and diabetes in experimental animals. Some species, including humans, are more resistant to these drugs than others (Table 32.4). Streptozotocin is commonly used in treating certain gastroenteric tumors, including glucagonomas; however, T1D rarely develops in these patients. Several compounds structurally related to streptozotocin and alloxan have been implicated as possible environmental agents contributing to T1D. Pyriminil (Vacor), an effective rodenticide, is highly diabetogenic in humans.[96] The TEDDY study is an international effort to substantiate the possibility that environmental chemicals are causative factors in the development of T1D.[97]

In summary, viruses and chemical agents have direct effects on pancreatic β cells and may therefore represent the causative factors that initiate the autoimmune process against these cells. The alternative hypothesis is that these agents potentiate a β cell–destructive process that is genetically determined or initiated by environmental factors.

Birth Weight and Growth Rate. Several studies suggest a positive association between T1D HLA risk and an increase in perinatal and postnatal growth.[34,98] HLA genotypes may be associated with intrauterine growth, independent of T1D risk.[99] Greater weight in the first years of life was associated with an increased risk for a first appearing islet autoantibody.[100] A higher rate of weight gain was associated with increased risk of progression from GADA first to T1D.[101] Furthermore, being overweight at 2to 10 years of age was associated with increased risk of progression from multiple islet autoantibodies to clinical onset of T1D.[102] Children with higher weight-for-height or body mass index during infancy or childhood have greater T1D risk.[103] T1D boys were significantly taller than healthy boys from 1 to 7 years before clinical onset, regardless of age at onset.[35]

KEY POINTS

- Two endotypes were discovered. The first is children who develop insulin autoantibodies (IAAs) as the first appearing autoantibody at 1–4 years of age, primarily in human leukocyte antigen (HLA) DR4-DQ8 children. IAA first may be related to enterovirus B prolonged shedding. The second is children who develop GAD65 autoantibodies (GADA) at 2–3 years of age, primarily in HLA DR3-DQ2 children. GADA first may be related to mastadenovirus infection. While the incidence of IAA first decreases with increasing age, the incidence of GADA first remains elevated.

TABLE 32.4 Viruses and Other Environmental Factors Implicated In Type 1 Diabetes Etiology and Pathogenesis

	COMMENT	
Factor	**Host**	**Diabetes in Animals**
Viruses		
Enterovirus B incl. Coxsackie B (RNA)	Human	Mice
Rubella virus (RNA)	Human	Hamsters
Mumps virus (RNA)	Human	None
Cytomegalovirus (DNA)	Human	Cytomegalovirus in rats
Echovirus (RNA)	Human	None
Ljunganvirus (RNA)	Human	Bank voles
Rotavirus (RNA)	Human	None
Diet and Nutrition		
Cow's milk protein/bovine insulin	Early introduction before 4 months of age	
Cereals/gluten	Early introduction before 4 months of age	
High-calorie carbohydrates		
Nitrosamine-containing foods		
Vitamin D deficiency		
Growth, Body Size, and Weight Gain	Excess stress on β cells (accelerator hypothesis)	
Psychological Stress	Possibly through changing the hypothalamic-pituitary-adrenal regulatory mechanism	
Hygiene Theory	Inadequate maturation of immune system and subsequent autoimmune reaction	
Toxins		
Pyriminyl (Vacor)		
Pentamidine isothiocyanate		
N-3-Pyridylmethyl-N'p'-nitrophenylurea (PNU)		

PATHOGENESIS

The pathogenesis of T1D is strongly associated with several immune abnormalities. These immune abnormalities, in particular autoantibodies directed against insulin, GAD65, IA-2, and ZnT8, are dynamic markers of an ongoing disease process. These pathogenic markers are useful for predicting and classifying T1D. HLA does not seem to influence the tempo of the disease process when progressing from a first to a second islet autoantibody.[76,104] The role of the HLA class II molecules in the immune response is to convey cell–cell interactions between T-helper (CD4+) lymphocytes and antigen-presenting cells (APCs) or B lymphocytes. The CD4+ T cell provides help to cytotoxic T lymphocytes (CD8+) as well as to B lymphocytes. The importance of the immune system to T1D pathogenesis is underscored by recent genome-wide association studies, which suggest that variants of genetic factors important to the immune response increase the risk of T1D.[72]

What are the factors that contribute to progression from multiple autoantibodies without dysglycemia (stage 1) and multiple autoantibodies with dysglycemia (stage 2) to clinical onset (stage 3)? First, the number of islet autoantibodies accelerates progression to stage 3.[105,106] In persistently autoantibody-positive children, higher IAA and IA-2A levels, but not GADA levels, increased the risk for stage 3.[107] Different risk scores have been developed to predict the time to stage 3 among subjects with multiple islet autoantibodies.[108-111] Islet autoantibodies are becoming widespread as biomarkers of autoimmune T1D, and an increasing number of subjects are detected in stage 1 or stage 2 T1D. The need for additional biomarkers to better predict the time to clinical onset will be needed in anticipation of treatment that will halt the pathogenesis at stage 1 or stage 2.

Humoral Immunopathophysiology

Islet Cell Antibodies. ICAs detected by indirect immunofluorescence analysis of frozen sections of human blood group O pancreas were the first indication of autoantibodies in T1D.[46] ICSAs (see Table 32.5) in newly diagnosed T1D patients were demonstrated in dispersed-cell preparations of rat or mouse pancreatic islets.[48] The observation that antibodies are capable of binding to living β cells is important, because it allows an answer to the question of whether islet autoantibodies either mediate immune effector mechanisms or directly affect the function of the β cells. The former phenomena include complement-mediated cytotoxicity and antibody-dependent cellular cytotoxicity.[49] Either mechanism could contribute to killing pancreatic β cells, provided that the *in vitro* phenomenon is also occurring in vivo. However, knowledge of the autoantigen has improved our understanding and detection of islet autoimmunity. Several assay systems are now in use to determine the presence of antibodies reactive with pancreatic islet cell autoantigens (Table 32.5). Autoantibodies to GAD65, IA-2, insulin, and the zinc transporter ZnT8 have replaced ICA (Fig. 32.5). One or more of these autoantibodies may be present in more than 95% of newly diagnosed T1D patients,[112,113] and they present variably during the prodrome of islet autoimmunity long before the clinical onset.

In order to provide unified comparative assays, standardization of IAA, GADA, IA-2A, and ZnT8A has been carried out since 1985[114] and continued through the Diabetes Antibody Standardization Program (DASP)[115] and Islet Autoantibody Standardization Program (IASP).[56,116] These results imply the value of GADA, IAA, IA-2A, and ZnT8A for screening high-risk populations, as well as classifying patients with diabetes.

Glutamic Acid Decarboxylase Autoantibodies. Glutamic acid decarboxylase is present mainly in pancreatic β cells and neuron cells. This enzyme produces γ-aminobutyric acid, which is stored in

TABLE 32.5 Methods to Detect Autoantigen-Specific Islet Cell Autoantibodies

	METHOD OF DETECTION			
Preparation	**RBA**	**ELISA**	**Autoantibody Abbreviation**	**References**

Islet cell antibodies (ICA) identify autoimmunity in children with new onset diabetes mellitus negative for other islet cell antibodies. *Pediatr Diabetes.* 2014;15:336–344. Used with permission.)

small neurotransmitter vesicles. Two isoforms are known: GAD65 and GAD67. GAD65, detected in and cloned from human islets after immunoprecipitation, is coded for by a gene on human chromosome 10.[52] The previously known GAD67, encoded by a gene on chromosome 2, shares 65% of the amino acids, but this isoform is not expressed in human β cells.

The frequency of GADAs in children with new-onset T1D is 70% to 80% (Fig. 32.5). Patients with GAD67 autoantibodies are almost invariably GADA-positive. GADA frequency in new-onset patients is little affected by the age at onset; however, in children younger than 10 years, more girls than boys have GADA. GADAs are evanescent, but less so than ICA. GADAs tend to be the most prevalent and persist for longer duration after the diagnosis of T1D when compared with other autoantigens. Almost 50% of patients with disease duration of 10 years may still be GADA-positive.

Any assessment of an individual's risk of developing T1D depends on the ability to accurately determine the presence of autoantibodies in a prospective analysis. This is particularly important, because GADA may appear temporarily in healthy individuals. Persistent GADAs are more often detected in subjects with *DRBI*03-DQA1*05:01-B1*02:01* than in those with *DRB1*04-DQ A1*03:01-B1*03:02.*[117] Truncated GADA may be present in both HLA haplotypes.[118] GADA may be detected in approximately 1% of the general population, but the frequency increases to approximately 8% among first-degree relatives of patients with T1D. The positive predictive value of GADA for T1D is approximately 50% or higher among first-degree relatives. GADAs also predict stiff person syndrome, although the GADA epitopes are different from those in T1D.[119] T1D is best predicted when GADA is combined with IAA, IA-2A, and ZnT8A.[25,120]

Insulin Autoantibodies. Insulin is produced after the C-peptide has been cleaved from proinsulin. The molecular weight of insulin is 5.8 kD, and the molecule is composed of the A and B chains. It was demonstrated in a radioligand binding assay that approximately 50% of patients with newly diagnosed but untreated T1D had IAAs.[53] Among children at T1D genetic risk and younger than 5 years of age, IAAs were reported to be the first appearing islet autoantibodies.[57,63,66] IAA is therefore the most common islet autoantibody in young children, but the frequency at diagnosis (stage 3) decreases with increasing age (Fig. 32.5). Proinsulin is viewed as a primary specific autoantigen, especially because it is unique to the β cells. IAAs react with both insulin and proinsulin, indicating that these proteins possess shared epitopes as targets of IAA.

IAAs were positively associated with DR4, perhaps because they are in linkage disequilibrium with *DQA1*03:01-DQB1*03:02.*[66,117] A first analysis of putative IAA epitopes indicates that the amino acids B1 to B3 and A8 to A13 are important.[121] IAAs and insulin antibodies that appear after insulin therapy have similar binding characteristics.[122]

IAA assays have been standardized, and only the fluid-phase radioimmunoassay (but not the enzyme linked immunosorbent assay [ELISA]) was found to have high diagnostic sensitivity and specificity for T1D. The fluid-phase radioimmunoassay for IAA is still lacking an international standard, and the IAA test is therefore yet to be standardized.[123]

Islet Antigen-2 Autoantibodies. Trypsin treatment of the 64-kD immunoprecipitate revealed 40-kD and 37-kD fragments of islet antigen, yielding two isoforms of IA-2A: IA-2 (ICA512) and IA-2β (phogrin).[54,124-126] IA-2 and IA-2β are both associated with the secretion granule membrane. These isoforms share high structural similarity but lack enzymatic activity, and their functions in neuroendocrine tissues such as the hypothalamus and pancreatic islets are not fully understood. IA-2As are detected in 60% to 70% of patients with new-onset T1D (Fig. 32.5), but in older patients IA-2As contribute less. Longitudinal studies of first-degree relatives suggest that IA-2As tend to appear closer to the clinical onset of T1D compared with GADAs. IA-2A is rarely a first appearing islet autoantibody.[63,66]

IA-2As were associated primarily with *DRB1*04:01* and not with *DQA1*03:01-DQBI*03:02,*[127] and the risk for this antibody is increased in males. Surprisingly, IA-2A in T1D was negatively associated with *DQA1 *05:01-DQBI*02:01.*[117] The mechanisms by which the IA-2 proteins become recognized as autoantigens are therefore not yet understood. The frequency of IA-2A in the general population is less than 1%. In young children with genetic susceptibility, progression to clinical T1D onset was associated with broad epitope response and juxtamembrane reactivity to the IA-2 antigen.[127]

The predictive value of IA-2A for T1D is best estimated in combination with GADA and IAA. ELISA tests for IA-2Ab are available, with similar diagnostic sensitivity and specificity to radioligand assays, and combination ELISA tests using biotin-labeled preparations of both IA-2A and GADA have been developed. IA-2Ab performance with ELISA was improved in DASP and IASP to achieve levels of equivalent to in-house results for radioimmunoassay (see Table 32.7).

ZnT8 TransporterAutoantibodies. The β cell–specific ZnT8 transporter was found not only to be the target of islet autoimmunity but also a genetic marker for T2D.[128] The ZnT8 transporter is important to the formation of insulin crystals in that it facilitates zinc transportation into the β cell insulin granules. This antigen is encoded by the *SLC30A8* gene, which is one of nine human genes for multispanning transmembrane proteins. Epitope mapping of these autoantibodies showed that ZnT8A primarily react with the C-terminal end of the protein.[129] Polymorphic variants of ZnT8 at amino acid position 325 in the cytosolic tail were found to be either arginine (ZnT8-R) or tryptophan (ZnT8-W), both representing markers of ZnT8A susceptibility with potential diagnostic, therapeutic, and prognostic uses.

ZnT8As were detected in 26% of subjects who were reported to be negative for GADA, IA-2A, and IAA. On the other hand, ZnT8As were found to be positive in 60% to 80% of newly diagnosed T1D patients (Fig. 32.5) but in only 2% of controls and less than 3% of T2D patients.[130]

ZnT8As were also found during the islet autoimmune prodrome, often after 2 years of age and independently of other autoantibodies, but mainly later than GADA and IAA.[63,66] The high specificity and independent appearance of ZnT8As highlight their usefulness for prediction, especially in older children and adolescents, as ZnT8Ab prevalence and titer levels increase with age.[25,112]

Following similar principles of GADA and IA-2A standardization, fluid-phase radioassays of ZnT8Ab (C-terminal) were standardized and validated in the DASP and IASP workshops (see Table 32.7).[116]

In summary, currently available methods for detecting autoantigen-specific autoantibodies (GADA, IA-2A, IAA, and ZnT8A) are of value in predicting T1D. Standardized assays for these autoantibodies are important when selecting participants for prevention and intervention trials. How the uptake, processing, and presentation of these autoantigens by APCs that initiate the formation of autoantigen-reactive T and B lymphocytes are accomplished are important questions that remain to be answered.

Candidate (Minor) Autoantigens. Several proteins or other substances implicated in T1D autoimmunity may represent candidate or minor autoantigens. Autoantigens reported to be associated with T1D include imogen38,[131,132] vesicle-associated membrane protein-2 (VAMP2),[133] neuropeptide-Y (NPY),[133,134], glima-38[135] representing TSPAN7,[136,137] heat shock protein 60 (HSP60),[138,139] ICA69,[140,141] carboxypeptidase H (CPH),[142] DNA topoisomerase II,[143] CD38 (ADP ribosyl cyclase/cyclic ADP-ribose hydrolase),[144] type-2 glucose transporter (GLUT-2),[145,146] and ICA12/SOX13.[147,148] The role of these candidate autoantigens in islet autoimmunity, T1D, or both, remains to be determined.

Cellular Immunopathophysiology

Pancreas Pathology. Studies of the pancreas in newly diagnosed T1D patients have indicated that the gland is diminished in size compared with that in matched controls.[149] An atrophic pancreas with little or negligible residual insulin is typical of a patient with longstanding T1D. The atrophy affects primarily the tail of the pancreas. In this part, the composition of the endocrine pancreas is dominated by β and α cells, whereas in the pancreatic head, β and pancreatic polypeptide (PP) cells predominate. In addition to insulin deficiency, the pancreatic atrophy appears to be reflected in lower serum levels of pancreatic trypsin and isoamylase.[150,151] It is speculated that the pancreatic atrophy is a result of an intrapancreatic insulin deficiency affecting the growth of the pancreas.

The insulin deficiency is the result of a specific loss of the β cells, which affects the total mass of the endocrine pancreas in T1D

TABLE 32.6 **Morphometric Analysis of the Endocrine Pancreas in Control Individuals and Patients with Type 1 Diabetes Mellitus (T1DM)**

	ENDOCRINE PANCREAS (μg)	
Cell T`ype	Controls	T1DM
β cells	850	0
α cells	230	150
δ cells	125	97

(Table 32.6). The islets are small and appear pseudoatrophic. In contrast to the normal pancreas, in which the β cells predominate, the endocrine cells in the diabetic pancreas are primarily α, δ, and PP cells. Lobular variation has been described, and areas with β cell–containing islets without pancreatic atrophy also have been detected, suggesting that parts of the pancreas may be spared in individuals with newly diagnosed T1D.[41] Sometimes β cells are seen in close proximity to duct cells, suggesting neoformation of cells. The understanding of the developing endocrine pancreas has improved, and a number of transcription factors controlling the process have been identified.[72] However, one of the characteristics of the pancreas in many children with newly diagnosed T1D is the presence of inflammatory cells adjacent to islets or cords of newly formed β cells.[152]

Immunocytochemical investigation in rare specimens of pancreas from patients who died shortly after the clinical onset of T1D indicates that all cell types considered part of the immune system populate the islets to form the insulitis.[41,152,153] T lymphocytes, B lymphocytes, macrophages, and occasional natural killer cells may be seen. In agreement with earlier studies, examination of pancreatic islets in laparoscopically obtained biopsy specimens from newly diagnosed T1D patients[43] demonstrated insulitis in approximately 60% of patients, with a T cell–predominant infiltration and increased expression of HLA class I.[154,155] Notably, the presence of insulitis was strongly correlated with the presence of other autoimmune features, specifically positivity for GADAs or IA-2As.[44] In contrast, examination of specimens from 1507 pancreatic donors aged 25 to 60 years revealed 62 (4%) islet autoantibody–positive subjects.[156] Insulitis was found in only two (3%) of the 62 subjects; the two subjects were positive for multiple islet autoantibodies and susceptible HLA. None of the 62 matched controls had insulitis. These results suggest that positivity for islet autoantibodies does not immediately mean that insulitis is present. Islet autoantibodies seem to precede insulitis and seem to require not only one but a concurrent presence of multiple islet autoantibodies.

Taken together, current observations support the hypothesis that T1D is an immune-mediated disease and that immunocytes play a pivotal role in the loss of β cells. It cannot be excluded that a diminished β cell mass alters the rate of insulin biosynthesis and secretion in remaining β cells, as well as insulin resistance in peripheral tissues.

Peripheral Blood Mononuclear Cells. It is possible that APC activity is altered in patients or in individuals susceptible to T1D. Blood monocytes in T1D patients may be defective in prostaglandin synthetase and dendritic cells from patients with T1D have a maturational and functional defect.[157] APCs from T1D patients secrete markedly higher levels of proinflammatory cytokines in response to a nonantigenic stimulus.[158] Also, healthy HLA DR3–positive subjects have an abnormally prolonged Fc receptor-mediated mononuclear phagocyte system.[159]

T lymphocytes are also important to the pathogenesis of T1D. The earliest demonstration involved tests for leukocyte migration inhibition or blast formation, suggesting that T1D patients may be sensitized to pancreatic antigens.[42] Several disorders of autoimmune character have been found to have an imbalance in the peripheral blood between T-helper (CD4+), cytotoxic (CD8+), and regulatory (CD4+CD25+) T-cells. The use of HLA tetramers makes it possible to detect and clone autoantigen-specific human T-cells.[160-162] Other approaches to detect T-cell reactivity against islet cell antigens, such as enzyme-linked immune absorbent spot, which measures cytokine secretion from individual T-cells, are being explored.[163] Studies on peripheral blood cells are rare in subjects later shown to seroconvert to either IAA first or GADA first.[63,66] Patterns of RNA extracted from whole blood indicated that T1D is characterized by early and longitudinal changes in gene expression to be associated with a natural killer cell signature with progression to clinical onset.[164] The timing of blood samples in children at increased genetic risk for T1D, during seroconversion to a first appearing autoantibody, during stage 1 and 2 as well as at stage 3, will be critical to identify peripheral blood cells involved in both the etiology and the pathogenesis of T1D. In conclusion, antigen-specific tests in HLA DQ– and HLA DR–matched T1D subjects and control individuals should eventually allow a proper test of the hypothesis that a specific immunoregulation abnormality involving β cell antigens is associated with the development of T1D.

DIAGNOSTIC CRITERIA

T1D was often thought to be a disorder of acute onset, and the clinical onset may be dramatic. Over the years, however, numerous reports have noted that signs of subclinical diabetes precede the clinical onset. In addition, in adult diabetes patients classified with T2D, a change sometimes occurs from an insulin-independent to insulin-dependent state.

T1D is said to have four major clinical phases: preclinical diabetes, overt diabetes, partial remission phase (honeymoon), and the chronic phase of lifelong dependency on injected insulin. Autoantibodies against GAD65, insulin, IA-2, or ZnT8, alone or in combination, may be present up to several years before the clinical onset, and predict T1D.[6,105] The clinical onset is not likely to occur until a major loss (80%–90%) of the islet β cells has occurred. Currently it is not possible to determine the human β cell mass or volume. β cell function tests are affected by both β cell mass and insulin sensitivity. It is therefore not possible to relate clinical onset to β cell mass, especially since some reports suggest that around 40% to 50% of β cells may be viable, owing to β cell regeneration at the time of overt hyperglycemia.

The occurrence of diabetic ketoacidosis (DKA) is more commonly seen with new-onset disease, especially in children younger than 4 years of age, but it is not specific to T1D and may also occur in T2D. DKA occurs invariably in different populations, ranging from 15% to 67% of patients in Europe and North America, whereas in the developing world, around 80% of children with T1D present initially with DKA.[165,166] Typically the child is acidotic with acetone fruity odor, air hunger and Kussmaul respiration, abdominal pain, nausea and vomiting, and polyuria and polydipsia. The child has hyperglycemia, glucosuria, ketonemia, and ketonuria. Without timely management, severe fluid and electrolyte depletion soon develop, with signs of hypoperfusion and deterioration in the level of consciousness due to cerebral edema that may lead to coma and death.

The basis for distinction between T1D and T2D is islet autoimmunity and the patient's dependence on insulin. Most patients have a history of polyuria, polydipsia, and unexplained weight loss. The American Diabetes Association and the International Society for Pediatric and Adolescent Diabetes have recommended diagnostic criteria for T1D (Table 32.1).

Glucose tolerance tests, both oral and intravenous, are being used to evaluate diabetic states. The OGTT is a diagnostic criterion (Table 32.1). Although glucose tolerance tests are more important in disorders of impaired glucose tolerance and T2D, they may also find an increased use in the prediction and diagnosis of T1D.

KEY POINTS

- The number of islet autoantibodies are associated with an accelerated progression to stage 3. In persistently autoantibody-positive children, higher insulin autoantibody and islet antigen-2 autoantibody levels, but not GAD65 autoantibody levels, increased the risk for stage 3.

PREDICTION

Highly effective, precise, and reproducible screening assays for HLA genotypes, as well as for GADA, lA-2A, ZnT8A, and IAA, are in use to detect individuals with autoimmune islet disease, often referred to as islet autoimmunity. Early detection of T1D serves several purposes. Among them is the distinct possibility that ketoacidosis associated with a dramatic and traumatic onset of T1D, in some cases leading to death, would be forestalled. Prediction and prevention of DKA is a rationale for islet autoantibody screening in the general pediatric population.[120] In addition, immunotherapeutic modalities for prevention of β cell destruction are under active investigation with both oral insulin[5,167,168] and anti-CD3,[169] with the hope that T1D may someday be a preventable disease.

The fact that clinical onset of T1D is preceded by a long "prediabetes" phase marked by islet autoimmunity biomarkers makes T1D a candidate for prediction and prevention. The predictive value of these autoantibodies varies with age, and combining more than one autoantibody increases the positive predictive value. The improved ability to measure autoantibodies against GAD65, IA-2, ZnT8, and insulin made it possible to predict T1D with up to 98% accuracy when ZnT8A was added to the arsenal of islet autoantibody tests.[105,170,171] A high predictive value of screening tests is critical to designing interventional studies. The levels of autoantibodies reflect the degree of aggressiveness of the autoimmune reaction and are related to persistence of positivity and subsequent progression into clinical disease.

HLA testing alone is not a primary indicator for the prediction of T1D, but it has a significant role when used with autoimmune markers to increase sensitivity of prediction among subgroups with moderate risk. However, adding HLA DQ did not affect the diagnostic sensitivity of islet autoantibodies.[25,172,173] Several other genetic loci have also been reported to be associated with T1D genetic risk, but their contribution was less than HLA (see Table 32.4).

PREVENTION

The ability to prevent or reverse autoimmune diabetes in laboratory animals has led to several prevention and intervention studies in humans. Studies in the NOD mouse and the BB rat showed that treatment with insulin or nicotinamide reduced spontaneous diabetes. These studies initiated large clinical trials, such as the Diabetes Prevention Trial-1, the Diabetes Prediction and Prevention Project, and the European Nicotinamide Diabetes Intervention Trial, all without effects (see following discussion). Preclinical studies in rodents may therefore not always be suitable to guide human trials.

Whether to choose a preventive or intervention strategy is a matter of debate, and is related to several factors. First, it has been suggested that intervention trials should be reserved for therapies with greater risk that need to be used on a small number of newly diagnosed patients within limited follow-up periods. Second, prevention trials may be implemented with safer therapies that can be used in the preclinical phase with longer periods of follow-up.

KEY POINTS

- Risk scores have been developed to predict the time to stage 3 among subjects with multiple islet autoantibodies.

PRIMARY PREVENTION

Primary prevention trials would target genetic high-risk groups such as infants with HLA high risk,[174] such as the POInT study,[5] or a positive family history, such as Trial to Reduce IDDM in the Genetically At Risk (TRIGR) study.[175] While the POInT study is ongoing, the randomized, placebo-controlled, double-blind trial testing the effects of cow's milk or hydrolyzed casein formulae following 6 to 8 months of breastfeeding failed to show a difference in the risk for a first islet autoantibody.[175] The NIP study is using oral docosahexaenoic acid, a fatty acid thought to prevent islet autoimmunity, given to the mothers as a supplement. Infants will be followed up until 9 years of age. The gluten-free diet trial, PREVFIN, tested the possible effect of eliminating gluten from the diet on the risk of T1D. It ended in 2002 with no observed effects on islet autoantibodies or disease progression.

KEY POINTS

- Islet autoantibodies are endpoints in ongoing primary prevention studies such as oral insulin to prevent the appearance of insulin autoantibody first or GAD65 autoantibody first in children with increased genetic risk for type 1 diabetes.

SECONDARY PREVENTION

Secondary prevention strategies recruit children with high HLA genetic risk with positive autoantibodies and children and young adults with multiple autoantibodies in either stage 1 or 2. The aim is to delay and suppress β cell destruction by aggressive immunity. Antigen-based secondary prevention trials using insulin as a specific antigen have been carried out. The Diabetes Prevention Trial-1 (DPT-1) was a large randomized trial of treatment efficacy that had two arms: parenteral insulin (high-risk subject, no placebo, completed in 2002) and oral insulin (moderate-risk subject, placebo-controlled, completed in 2005) showed no effect in either arm.[176,177] A subanalysis of the oral arm gave strong evidence on reducing the incidence of T1D in relatives with insulin autoimmunity (IAA ≥80 U). A repeat study in autoantibody-positive relatives of patients with T1D, oral insulin at a dose of 7.5 mg/d, compared with placebo, did not delay or prevent the development of T1D over 2.7 years.[167] Nicotinamide (vitamin B_3) was used orally as a non–antigen-specific agent in the European Nicotinamide Diabetes Intervention Trial (ENDIT) but showed no effect on T1D outcome.[178] The Diabetes Prediction and Prevention Project (DIPP) was a randomized, placebo-controlled trial implemented in Finland;

it showed no effect in high–genetic risk children of intranasal insulin on the prevention of T1D.[179] GAD-alum as a subcutaneous prime and boost injection was safe in stage 1 and 2 children but did not affect progression to T1D.[180] Anti-CD3 (teplizumab) was used in a secondary prevention trial, and fewer participants in the teplizumab group compared with the placebo group were diagnosed with T1D.[169] The protective effect was predominantly observed in HLA DR3–negative, HLA DR4–positive subjects and among those negative for ZnT8A. Other trials that used cyclosporine, vitamin E, or intensive insulin treatment in combination with nicotinamide were without effects.

KEY POINTS

- Secondary prevention strategies recruit children and young adults with multiple autoantibodies in either stage 1 or stage 2. Anti-CD3 (teplizumab) had fewer participants with a type 1 diabetes diagnosis than the placebo group. The protective effect was predominantly observed in human leukocyte antigen (HLA) DR3–negative, HLA DR4-positive subjects and among those negative for zinc transporter 8 autoantibody.

INTERVENTION

Intervention or tertiary prevention trials target newly diagnosed T1D patients, aiming at preserving the residual β cell mass and enhancing β cell functionality and regeneration. Like prevention trials, intervention trials can also be either antigen-specific or non–antigen-specific. Immunomodulating injections with specific islet autoantigens have been adopted by several trials.

- The altered peptide ligand (APL) insulin B:9-23, NBI-6024, at repeated doses of 0.1, 0.5, or 1.0 mg did not improve or maintain β cell function.[181]
- DiaPep277 was an immunomodulatory HSP60 peptide given subcutaneously to subjects with new-onset T1D. All publications were retracted.[182]
- GAD65 formulated with alum has been used in randomized, placebo-controlled immunomodulation trials in LADA[183] and 10- to 18-year-old T1D patients in stage 2[184,185] and stage 3,[186] with possible preservation of residual β cell function. Recent analyses suggested that GAD-alum responders are to be found among HLA DR3–positive patients.[187,188] Intranodal injections as an alternative to subcutaneous injections are being attempted in controlled clinical trials.[189]
- A DNA plasmid encoding proinsulin (BHT-3021) was tested in 80 T1D patients to test if the treatment would reduce CD8+ T cells in the peripheral blood. C-peptide levels were preserved, and CD8+ T-cells declined.[190]

The non–antigen-specific approach has been used in numerous interventional studies. Randomized, placebo-controlled trials with oral cyclosporin-A showed reduced loss of residual C-peptide and insulin dosages; however, the effects were transient, and side effects outweighed the benefits.[191-193] Although azathioprine trials showed no effects when used alone, its combination with prednisone showed partial, temporary remission of new-onset T1D.[194] Antithymocyte globulin, used in organ transplantation, showed reduction in insulin requirements when combined with prednisone, but severe, transient thrombocytopenia emerged as a major side effect.[195] The CD3ε monoclonal antibody otelixizumab preserved β cell function but showed dose-dependent Epstein–Barr virus activation.[196] The CD3 monoclonal antibody teplizumab, which suppress T-cell activity by blocking T-cell proliferation and differentiation, preserved insulin production and reduced exogenous insulin in some patients with new-onset T1D.[197,198] Costimulation modulation with abatacept preserved β cell function and improved HbA1c in recent-onset T1D. The effect was sustained for at least 1 year, or 3 years from T1D diagnosis.[199]

The anti-CD20 agent rituximab is a monoclonal antibody that reduces blood B-cells by blocking the CD20 receptors and showed transient preservation of residual β cell function.[200,201] Combination therapies have been rare. However, anti–IL-21 and liraglutide in combination only could preserve β cell function in recently diagnosed type 1 diabetes.[202]

Tertiary intervention includes both whole-organ pancreatic transplantation and isolated islet transplantation. Both approaches have proved successful in terms of restoring glycemic levels and insulin independence, but isolated islet transplantation had lesser glycemic control, transient effects, increased morbidity, and higher costs.[203]

SUMMARY AND FUTURE DIRECTIONS

The islet β cells are the specific targets in an autoimmune process that eventually leads to the clinical onset of T1D. The etiology is related to HLA DR-DQ genetic factors, which are necessary but not sufficient for disease development. The environmental etiology is related to enterovirus infection in early childhood, resulting in two endotypes. In HLA DR4-DQ8 subjects, prolonged shedding of enterovirus B may induce autoantibody biomarkers against insulin (IAA). In HLA DR3-DQ2 subjects, other gastrointestinal viruses may initiate autoantibodies against glutamic acid decarboxylase (GADA). In 60% of children, initiation of islet autoimmune pathogenesis is followed within 1 year by a second autoantibody, including IAA, GADA, IA-2A, or ZnT8A. Two or more islet autoantibodies predict clinical onset in 70% of subjects within 10 years. The pathogenesis may be related to several non-HLA genetic factors, as well as to environmental factors. The β cell destruction by cellular immunity (insulitis) appears late and is related to prediabetic metabolic disturbances prior to overt diabetes. The aim of future prevention and intervention studies in humans is to test whether antigen-specific immunosuppression or other immunomodulatory therapies in T1D-susceptible individuals will prevent the loss of pancreatic β cells.

INTRODUCTION

The term "type 2 diabetes mellitus" (T2D) is often erroneously thought to refer to a discrete disease entity that has a specific cause and therapeutic approaches that can be used to target and reverse its pathophysiologic consequences. However, this term more accurately describes a heterogeneous, polygenic syndrome. The most prominent features are fasting and postprandial hyperglycemia without an unmitigated progression to ketoacidosis, often combined with hyperlipidemia, and with onset in middle life, although the disease can initiate in childhood or adolescence, as well as in the elderly. In addition, T2D lies within the broader context of cardiometabolic disease (CMD), with progression to cardiovascular disease (CVD) and nonalcoholic fatty liver disease (NAFLD). Both a previous term (non–insulin-dependent diabetes mellitus) and the current term (T2D) were created to distinguish this syndrome from type 1 diabetes (T1D). The latter disease (see Chapter 32) is a more clearly definable disease entity for which laboratory-based measurements implicate both autoimmune and genetic causations.

EPIDEMIOLOGY

T2D accounts for more than 90% of patients with diabetes and is an increasing cause of morbidity and mortality. In 2019, approximately half a billion individuals had T2D, which amounted to 9.3% of adults worldwide.[1] Prevalence rates rise as a function of age, with 4.4% of individuals affected aged 15 to 49 years, 15% aged 50 to 69 years, and 22% aged 70 years and above.[2] Incidence rates rise progressively up to age 55 to 60 years, and the gender distribution is approximately equal. Over 1 million deaths per year internationally can be attributed to diabetes alone, making it the ninth leading cause of mortality, although diabetes heavily contributes to mortality ascribed to other disease processes such as CVD, NAFLD, dementia, kidney disease, and cancer. In the United States,[3] 13% of adults had diabetes in 2018, and 21% of these individuals were unaware that they had the disease. Eighty-nine percent of individuals with T2D have overweight or obesity, and 38% were physically inactive. One in three US adults has prediabetes, which is of concern because conversion to overt diabetes occurs at a rate of greater than 5% per year,[4] although this varies as a function of associated risk factors.[5] The burden of diabetes mellitus is rising globally. Prevalence in adults is projected to increase by 25% in 2030 and 51% by 2045,[1] and the increasing number of children and adolescents who are developing T2D is particularly problematic. These data point to the need for concerted efforts at disease prevention.

KEY POINTS

- Type 2 diabetes accounts for 90% of diabetes and is a polygenic complex syndrome rather than a specific disease. It affects 9.3% of adults worldwide, and directly accounts for over 1 million deaths/year worldwide.

ORIGINS OF THE DISEASE: ETIOLOGIC FACTORS

T2D is a complex chronic disease that is the result of variable interactions among genetic, behavioral, biological, and environmental factors, as illustrated in Fig. 33.1. Because of this complexity, T2D presents as a heterogeneous disorder. While all patients are characterized by hyperglycemia, the physical and metabolic phenotype of the disease can vary as a function of age, region and ethnicity, body mass index (BMI), distribution of adipose tissue depots, syndromic features in patients with mono/oligogenetic disease, propensity for vascular complications, and the degree to which insulin resistance and impaired insulin secretion contribute to hyperglycemia.

Region, Race, Ethnicity, and Genetic Factors

T2D variably impacts global regions, countries, and ethnic and racial groups. Globally, Middle East and North Africa have the highest diabetes prevalence rates, followed by the Western Pacific and Southeast Asia.[1] Prevalence rates are particularly high in West Pacific Island and Arabic countries. The country with the highest number of diabetes patients is China, followed by India, the United States, and Pakistan. In countries with diverse populations, diabetes disproportionately affects specific ethnic and racial groups. In the United States,[3] prevalence rates are increased 2-fold in Native Americans, 1.6-fold in non-Hispanic Black Americans and people of Hispanic origin, and 1.2-fold in non-Hispanic Asian Americans compared with non-Hispanic White Americans. In addition, T2D prevalence rates among youth are increasing most dramatically in non-Hispanic Black Americans and Hispanics. Fig. 33.2 shows county-by-county diabetes prevalence rates across the United States and the increments in prevalence from 2004 to 2016. Due to high concentrations of the disease in Appalachia and the southern tier of states, the Centers for Disease Control has termed this region the “Diabetes Belt.”[6]

There is a strong genetic contribution to the development of T2D, as evidenced by five lines of investigation: (i) racial aggregation, (ii) familial aggregation and segregation, (iii) twin studies, (iv) relatively uncommon monogenic forms of diabetes such as maturity onset diabetes of the young (MODY), and (v) the identification of susceptibility alleles in candidate gene and genome-wide association studies (GWAS).

Evidence for the Genetic Basis of Type 2 Diabetes: Race, Family, and Twins. Racial aggregation is exemplified by racial or ethnic groups with defined ancestral origins having higher prevalence rates of diabetes than other subpopulations living in a comparable environment. Examples include higher diabetes rates in Black, Hispanic, and Japanese Americans compared with the general US population.

T2D also has a strong family history. Sibling recurrence risk ratio (λ_s) is a measure of familial aggregation that is operationally defined as the proportion of affected siblings of affected individuals compared with the general population. This ratio varies among populations, but generally the relative risk is approximately 1.5 to 2.0 for T2D.[7] The risk of developing T2D in a child with a parent who has diabetes is one in seven if the affected parent was diagnosed under 50 years of age, and one in 13 if diagnosed when older than 50 years. Some studies indicate that risk of T2D in offspring may be somewhat higher if the affected parent is the mother. If both patients have T2D, the risk in a child increases to approximately 50%.

Some of the strongest evidence for the genetic basis of T2D derives from twin studies.[8-10] These studies have demonstrated higher rates of concordance for T2D in monozygotic twins (80%–95%) who share 100% of their DNA compared with lower concordance rates (30%–40%) in dizygotic twins who share only 50% of their DNA. Despite strong family history and concordance rates in twins, the inheritance pattern of common T2D does not conform to any recognizable Mendelian pattern. Thus, T2D in the vast majority of patients is not the result of a single gene defect, but rather a polygenic disorder that results from the inheritance of multiple genetic mutations, each with a small effect size. This can account for phenotypic heterogeneity within T2D, because individuals inherit different subsets of susceptibility genes that interact in varying ways with different environmental factors.

Genetic Studies: Candidate Gene and Whole-Genome Approaches. The candidate gene approach begins with identifying key proteins highly relevant to glucose homeostasis and then assessing whether corresponding genes display polymorphisms that are associated with diabetes. A refined candidate gene approach conducts similar analyses on metabolic subphenotypes, such as proteins relevant to insulin secretion or insulin action, with the presumption that these traits are less polygenic and more proximal manifestations of genetic defects causing diabetes. Genetic studies using candidate gene approaches and linkage analyses have identified several T2D-associated loci, including peroxisome proliferator activated receptor γ (PPARG), inwardly rectifying Kir6.2 component of the pancreatic β cell adenosine triphosphate–dependent potassium channel (KCNJ11), transcription factor 7–like 2 (TCF7L2), and wolframin (WFS1).[11]

GWAS examine single nucleotide polymorphisms (SNPs) or other types of genetic markers interspersed throughout the genome and identify which polymorphisms may be associated with a disease in a large case-control cohort. Specific disease-associated polymorphisms serve as markers of potential causal genes at their respective chromosomal loci. Nucleotide sequencing or positional cloning techniques are then used to identify specific genes with causal mutations within each associated locus. GWAS have employed increasing sample sizes as consortia have been formed to combine genomic and phenotypic data from multiple studies, and over 400 SNPs at loci throughout the genome have been associated with T2D.[12-14] For example, a metaanalysis combined GWAS data from the Diabetes Genetics Replication and Meta-analysis, Genetic Epidemiology Research on Aging, and the full-cohort release of the UK Biobank to establish a database of 62,892 patients with T2D and 596,424 unaffected controls.[13] This study identified 139 common and four rare SNPs independently associated with T2D, including 39 variants reaching genome-wide significance that had not previously been reported. Pathway analyses showed that loci associated with T2D contained genes that were most highly enriched in molecular pathways involved in glucose homeostasis and MODY. Further functional enrichment incorporating protein–protein interactions pointed to four genes involved in insulin secretion (*ADCY5*, *CAMK2G*, *KCNJ11*, and *KCNU1*) and another four relevant to MODY (*HHEX*, *HNF1A*, *HNF1B*, and *FOXA2*). This study and others have demonstrated that identified susceptibility alleles individually confer only a small relative risk for diabetes (generally <1%) and in aggregate explain only a small proportion (<10%) of T2D heritability. Of these polymorphic loci, the preponderance of genes associated with T2D and abnormal glucose tolerance are involved in pancreatic islet development and regulation of insulin secretion, including *CDKAL1, KCNQ1, IDE, HHEX, ABCA1, ABCC8,* BCL11A, TCF7L2, SLC30A8, HHEX/IDE, and KCNJ11.[12,14,15] The strongest genome-wide association signals were observed for SNPs in *TCF7L2*,[16] a gene involved in the WNT signaling pathway and affecting pancreatic β cell function.[17] This is consistent with the heritability factor for the insulin secretory defect, estimated to be as high as 70%.[18-20] The heritably scores (h^2) for insulin resistance are generally more modest, in the range of approximately 30%.[18,19] Nevertheless, several chromosomal regions have been found to associate with various measures of insulin resistance in GWAS, such as *PPARG, IRS1, NAT2, IGF1, BCL2,* and *FAM19A2*.[21-24] Again, each of these genes individually confers only a small relative risk for impaired insulin secretion and insulin resistance, which are considered key mechanistic subphenotypes of T2D. The relatively low heritability scores for insulin resistance indicate that factors such as physical inactivity and diets enriched in saturated fats, refined grains, and low fiber could be responsible for a substantial amount of individual variation in insulin sensitivity.[25]

There is a strong heritability component to BMI that varies between 40% to 70%,[26,27] and over 100 susceptibility genes for elevated BMI have been identified in GWAS studies.[28,29] The vast preponderance of susceptibility genes for obesity do not overlap with those associated with insulin resistance or diabetes,[30,31] suggesting that, while interactions are operative in the expression of these traits, obesity and insulin resistance largely segregate independently regarding genetic risk. The fat mass and obesity–associated (*FTO*) and melanocortin-4 receptor (*MC4R*) genes are exceptions, in that mutations in these genes are associated with both elevated BMI and diabetes.

With advances in nucleotide sequencing and throughput, large-scale sequencing has been conducted of entire genomes or of all exomes that contain the protein-coding component, estimated to comprise less than 2% of the genome. Exome sequencing promises to enable the identification of causal genes within GWAS loci, and also of rare variants not detectable by GWAS.[32-34] The T2D-Genes Consortium has endeavored to conduct exome sequencing in patients with T2D and controls across five ethnicities: Black, South Asian, East Asian, Hispanic, and European. Investigators have reported analyses of 20,791 individuals with T2D and 24,440 nondiabetic control participants in aggregate from the T2D-Genes Consortium and five additional consortia.[32] These authors found 2.26 million variants associated with T2D leading to a change in amino acid sequence (i.e., nonsynonymous), and 93.5% of these were rare, having an allele frequency of less than 0.5%. Rare variants reaching genome-wide significance included a novel mutation in a known gene (*MC4R*), a novel gene (*UBE2NL*), and several other genes known to be associated with T2D risk (e.g., *SLC30A8, PAM*). Interestingly, the rare alleles together could explain far less risk than that conferred by common variants, indicating that a significant component of T2D risk cannot be explained by unknown rare variants with high effect size. Of 595 genes within known GWAS loci, 40 were associated with T2D in the exome data, and only 14 of these genes represented the named gene given to this locus, which underscores the hazards of assuming an attractive candidate within a GWAS locus is actually responsible for the association. Other genes not quite reaching whole-exome significance were grouped into functional sets and found to be of sub–exome-wide significance, including multiple drug targets (*GLP1R, IGF1R, PPARG, INSR, SLC5A2, DPP4,* and *ABCC8*). This landmark study[32] still leaves unexplained the question of missing genetic factors needed to fully explain heritability; this perhaps will require more sophisticated analyses of multiple gene interactions and interactions with environmental factors.

Epigenetic Factors. There is increasing interest in the epigenetics of diabetes as a mechanism by which changes in DNA or chromatin structure can alter gene expression without involving alterations in nucleotide sequence. Epigenomics refers to genome-wide studies that focus on three processes: (i) DNA methylation, primarily on cytosine residues present at CpG sites, that can result in suppression of gene expression when occurring in promoter or enhancer regions; (ii) modification of histone proteins by acetylation, methylation, sumoylation, or ubiquitination, which alters chromatin remodeling required for gene transcription; and (iii) noncoding RNAs (e.g., microRNAs) that can interfere with mRNA processing or translation. Each of these mechanisms has been shown to alter cellular biology in ways that are relevant to diabetes pathogenesis.

The alterations in DNA and histone structure can be inherited from maternal or paternal germ cells or arise *de novo* in a tissue specific manner. Importantly, epigenetic changes can be induced by nutritional and environmental factors,[35,36] providing a mechanism by which environmental exposures can produce persisting changes in metabolism over the lifespan. In humans, circulating white blood cells provide a convenient source of material for epigenetic studies; however, these changes may not reflect epigenetic modifications and effects on gene expression in metabolically relevant tissues.[37] Even so, investigators have used genomic DNA from white blood cells in T1D patients enrolled in the Diabetes Control and Complications Trial/Epidemiology of Diabetes Interventions and Complications study and have shown that persisting methylation at key CpG sites was associated with hemoglobin A1c (HbA1c).[38] This observation provided a potential explanation for "metabolic memory," by which a previous period of intensive glycemic control could provide benefits with continued follow-up long after the intervention. Animal studies allow for the study of epigenetic changes and corresponding effects on gene expression within relevant tissues. For example, studies of genome-wide methylation patterns in pancreatic β cells from young and old mice found that methylation of proliferative gene loci contributes to a decline in insulin secretory capacity that is recapitulated by epigenetic changes identified in human islets obtained from patients with T2D.[37,39,40]

Accumulating evidence indicates that differential CpG methylation can occur as a function of the *in utero* environment and participate in the programming of body weight and metabolism in offspring into adulthood, allowing for the intergenerational transmission of metabolic phenotypes. Epigenetic modifications have been implicated that alter body composition and metabolism in offspring and that confer insulin resistance and increased risk for T2DM, obesity, and CVD persisting into adulthood.[41-44] These studies assess epigenetic modifications using cord blood or placenta at birth and have identified changes in the methylation of genes involved in inflammation, insulin signaling, and leptin.[45-49] These studies have demonstrated that gestational diabetes is associated with differential methylation of *MEST, NR3C1,* and *LEP* in offspring compared with children born to glucose-tolerant mothers, associated with greater insulin and leptin concentrations. Fetal hyperinsulinemia due to intrauterine exposure to gestational diabetes or obesity persists into childhood and adolescence, consistent with the hypothesis that insulin sensitivity and secretion are programmed *in utero.*[50]

Methylation of CpGs is mediated by DNA methyltransferases, but these changes are reversible via the action of a family of ten-eleven translocation enzymes. Demethylation of key CpG islands can be induced by weight loss interventions involving exercise, diet, and weight loss surgery.[51-53] Interestingly, genes involved in obesity, insulin receptor signaling, T2D, and leptin signaling were differently methylated in children born before versus after their mothers' bariatric surgery–associated weight loss.[52,53] Clearly, epigenetics provides mechanisms by which environment and behavior lead to persisting alterations in gene expression that can contribute to pathogenesis or reduce the risk of T2D.

Noncoding RNA species also play a role in T2D. MicroRNAs are short noncoding RNA molecules usually consisting of a maximum of 22 nucleotides that bind complementary target mRNAs in the RNA-induced silencing complex and either degrade the target mRNA or block its translation. MicroRNAs can act locally within tissues and cells to regulate gene expression or be released into the circulation, protected from degradation in exosomes or by adherence to circulating proteins. Circulating miRNAs can be targeted for uptake by specific cell types and alter gene expression in the host cell,[54] thus constituting a mechanism for intertissue communication.[55,56] MicroRNAs can play a regulatory role in normal metabolic homeostasis, but also contribute to disease processes, as described in more detail in Chapter 30. Work in humans has most often focused on blood levels of microRNAs, and multiple species have been identified that correlate with diabetes, obesity, and other metabolic traits.[57-60] As an example, circulating miR-150 levels in humans are elevated in insulin resistance (i.e., negatively correlated with clamp measures of insulin sensitivity).[57] In cultured cell systems and rodent models, miR-150 has been shown to regulate lipid metabolism and inflammatory responses[61] and attenuate the browning process in adipocytes.[62] One of the targets of miR-150 is pgc-1α,[62] which is known to be involved in lipid metabolism and adipocyte browning, and pgc-1α in turn upregulates peroxisome proliferator–activated receptor α (PPARα), a key transcription factor affecting fatty acid (FA) oxidation.[63] An increase in miR-150 could reverse these processes by suppressing expression of pgc-1α. In intact mice, total body knockout of miR-150 reduced whole-body fat mass, improved systemic glucose tolerance and insulin sensitivity, and reduced production of proinflammatory cytokines in adipose tissue.[64] More definitive work is required to address mechanisms by which changes in circulating microRNAs contribute to T2D. Nevertheless, this field is promising, because microRNAs can potentially serve as biomarkers, or even as therapeutic agents by intravenous administration.[65-67]

Environment and the Social Determinants of Health

It is well documented that social and environmental factors are associated with higher rates of diabetes and help explain differences in prevalence and health disparities in populations.[68] Low socioeconomic status and reduced economic viability are associated with greater diabetes risk. This is often accompanied by a lower education level affecting capacity for income generation, health literacy, and access to care determined by lack of health insurance, ability to afford care, availability of health care professionals, and transportation. The built environment can contribute to higher diabetes prevalence when there is lack of access to unprocessed food and resources enabling physical activity. Social support systems and public health messaging are additional factors that have been well documented to impact outcomes of chronic disease. Sociopolitical factors can generate discrimination based on age, ethnicity, social class, and other attributes, which produces disenfranchisement and both actual and perceived stress. These determinants not only dictate access to resources and the capacity to prevent and/or manage diabetes, but also contribute to psychological stress and depression, which have been linked to poor diabetes outcomes.

Behavior and Culture

Lifestyle patterns based on personal or cultural preferences have a substantial impact in the pathogenesis of diabetes, particularly in relation to nutrition and physical activity. Recommendations for a "healthy meal pattern" generally include: (i) limitations on fat intake; (ii) emphasis on poly/monounsaturated fats over saturated fats; (iii) no *trans* fats; (iv) avoidance of added sugar and sugar-sweetened beverages; (v) complex over simple carbohydrates; (vi) whole grains; (vii) fruits and vegetables; (viii) dietary fiber, (ix) limited sodium intake; (x) moderation in alcohol; (xi) reduced consumption of processed food.[69] These recommendations are largely supported by epidemiological data, while long-term controlled clinical trials specifying progression to T2D and CVD events as primary outcomes are lacking. Fortunately, there is a large body of data indicating that isocaloric substitution of specific macronutrients can influence insulin sensitivity and CVD risk factors. Specifically, isocaloric enrichments or substitutions of macronutrients have been demonstrated to increase insulin sensitivity (mono- and polyunsaturated fats, whole grains, high fiber, low glycemic index) or worsen insulin resistance (saturated and trans fats, refined grains, low fiber, high glycemic index) in studies employing glucose clamps for measurement of insulin sensitivity.[25] Similarly, physical inactivity and a sedentary lifestyle augment diabetes risk, and this can occur independent of obesity.[25] Importantly, lifestyle interventions have been shown to prevent progression to diabetes among patients at high risk and to reduce glycemia or even produce disease remission among patients with overt T2D. This includes exercise programs or meal patterns such as the Mediterranean diet[70,71] that can reduce T2D risk even without weight loss, and lifestyle modifications producing weight loss in patients with overweight or obesity.[72] As an example of the latter, the Diabetes Prevention Program demonstrated that weight loss as a result of a reduced calorie diet and exercise in patients with impaired glucose tolerance prevented progression to diabetes by 58% compared with placebo.[73]

KEY POINTS

- Type 2 diabetes is highly inheritable and highly polygenic. Genome-wide association studies have identified over 400 susceptibility loci, each conferring only a small relative risk for the disease and, in aggregate, explaining <10% of diabetes risk. More research is warranted addressing gene–gene and gene–environment interactions and epigenetic factors.

Cultural identification and acculturation regarding diet and food preferences and emphasis on physical activity are important determinants and can affect T2D risk in individuals as well as populations. The influence of culture and lifestyle is underscored by the change in diabetes prevalence when ethnic groups migrate from a rural to an urban environment or from an agrarian society to a more sedentary, developed, or "Westernized" society. This is exemplified by Gullah-speaking Black Americans living in the South Carolina low country compared with the genetically-related ancestral population in Sierra Leone, West Africa.[74] Gullah-speaking Black Americans have high rates of T2D characterized by relatively high rates of diabetic complications, early age of onset, and a high relative risk to siblings of T2D (λ_S=3.3) and consume a diet rich in animal fats.[75,76] This is compared with a lower diabetes prevalence in Sierra Leone, where diets are high in carbohydrates.[77] Another example is the group of Pima Indians who moved from northern Mexico to southern Arizona approximately 2,000 years ago and since the early 1900s have adopted a more sedentary and "Westernized" lifestyle.[78-80] The Pima Indians who continue to live in northern Mexico and have retained an agrarian lifestyle have a diabetes prevalence of 6.9%, which is less than one-fifth the value of 38% in the Arizona Pima who also have higher rates of obesity. These lifestyle changes in Gullahs and Pimas predispose to the development of obesity, which is a major factor in the development of diabetes, as is discussed below.

Biological Factors

Biological factors unrelated to diabetes also affect diabetes pathogenesis, including aging, menopause, concurrent diseases, birth weight, and effects of the *in utero* environment on offspring. The prevalence of T2D rises progressively with age, although the incident rate increases up to approximately 60 years of age before slowly declining over the next several decades. The increase in T2D risk can at least partially be explained by an age-related decline in both insulin sensitivity and insulin secretion leading to a worsening of glucose tolerance,[81] together with a reduction in physical activity, decrease in muscle mass, and increase in percent body fat. Menopause in females can also be associated with an increase in total and intraabdominal fat, a reduction in physical activity, dyslipidemia, and insulin resistance.[82]

Low birth weight is a risk factor for the development of insulin resistance and diabetes mellitus later in life.[83] The mechanisms responsible for this association are unknown but may be related to epigenetic fetal adaptation to nutritional stimuli or excess fetal glucocorticoid exposure. For example, among a group of 60 adults with low birth weight and prenatal exposure to famine during the Dutch Hunger Winter in 1944 to 1945, there was less DNA methylation of the imprinted insulin-like growth factor 2 (*IGF2*) gene 60 years later compared with unexposed, same-sex siblings.[84] Even in normal-weight neonates, the *in utero* environment in mothers with gestational diabetes or obesity can produce an insulin-resistant phenotype in offspring.[41-44] Maternal health has become recognized as an important factor in decreasing rates of diabetes, obesity, and CVD.

KEY POINTS

- Type 2 diabetes (T2D) pathogenesis involves complex interactions among genetic and epigenetic factors, ethnicity, behavior, cultural practices, environment, biological factors, and social determinants of health. These varied interactions underlie the clinical heterogeneity of T2D.

Finally, a host of comorbid diseases can predispose to T2D. Many of these diseases worsen insulin resistance or impair insulin secretion, and include hormonal and metabolic disorders, lipoatrophy, pancreatic disease, iatrogenic medications, and genetic syndromes. The reader is referred to Table 33.1 and Chapter 35 for more extensive information.

NATURAL HISTORY OF DIABETES AS AN EVOLVING GLUCOREGULATORY DEFECT

Diagnosis of Type 2 Diabetes

The onset of T2D is most often insidious, with unexplained weight loss, lethargy, blurred vision, and polyuria; however, up to a third of patients remain undiagnosed and are unaware of the disease. Prediabetes can be identified[85] on the basis of: (i) impaired fasting glucose (IFG) with fasting glucose levels of less than or equal to 100 mg/dL (5.6 mmol/L); (ii) impaired glucose tolerance (IGT) diagnosed when 2-hour blood glucose levels are greater than 140 mg/dL (7.8 mmol/L) but less than 200 mg/dL (11.1 mmol/L) during a 75-gram oral glucose

TABLE 33.1 Unusual Phenotypes of Type 2 Diabetes

Category	Disease	Chapter/Reference
Genetic defects of β cell function	Maturity onset diabetes of the young (MODY) 1–6	Chapter 31
	Neonatal diabetes	Chapter 31
	Mitochondrial diabetes	*(i)*
Genetic defects in insulin action	Severe insulin resistance type A	Current chapter
	Leprechaunism, Donohue Syndrome	*(ii)*, *(iii)*
	Rabson–Mendenhall Syndrome	*(iv)*
Immune mechanisms	Severe insulin resistance type B	Current chapter
	Latent autoimmune diabetes in adults	Chapter 31
	"Stiff person" syndrome	*(v)*
Phenotypical features transitioning between type 2 diabetes and type 2 diabetes, depending on stage of disease	Latent autoimmune diabetes in adults (LADA)	Chapter 31
	Atypical diabetes	*(vi)*
Pancreatic disease	Cystic fibrosis	Chapter 35
	Chronic pancreatitis	Chapter 35
	Pancreatectomy	Chapter 35
	Tropical fibrocalculous diabetes	Chapter 35
Lipoatrophy	Generalized lipodystrophy	Chapter 24
	Partial lipodystrophy	Chapter 24
	Nonclassical patterns of lipodystrophy, e.g., type 2 diabetes and partial lipodystrophy of the limbs	*(vii)*
Metabolic disease	Hemochromatosis	Chapter 35
	Pseudoacromegaly	Chapter 35
Endocrinopathies	Hypercortisolism, acromegaly, hyperthyroidism, aldosteronoma	Chapter 35
	Polycystic ovary syndrome	Chapter ?
Drug-induced	Vacor, glucocorticoids, diazoxide pentamidine, nicotinic acid, thiazides, β-adrenergic agonists, dilantin, interferon, antiretrovirals	Chapter 35
Infections	Congenital rubella, cytomegaovirus	*(viii)*
Secretory neuroendocrine tumors	Somatostatinoma, glucagonoma, pheochromocytoma	Chapter 35
Genetic syndromes with increased incidence of diabetes	Down syndrome, Klinefelter syndrome, Turner syndrome, Friedreich ataxia, Wolfram syndrome, Huntington chorea, Laurence–Moon–Biedl syndrome, porphyria, Prader–Willi syndrome, progeria, Werner syndrome, Alström syndrome, myotonic dystrophy, mandibuloacral dysplasia	*(ix)*

tolerance test (OGTT); and/or (iii) with HbA1c values of 5.7% to 6.4% (39–47 mmol/mol). The diagnosis of T2D requires fasting glucoses greater than or equal to 126 mg/dL (7.0 mmol/L), 2-hour OGTT values of greater than or equal to 200 mg/dL (11.1 mmol/L), and/or HbA1c greater than or equal to 6.5% (48 mmol/mol). Unlike T1D, exogenous insulin is generally not required to sustain life in T2D, and patients do not develop diabetic ketoacidosis except under conditions of high biological stress. Nonetheless, many T2D patients use insulin to improve their glycemic management. Patients with T2D experience declining insulin secretory function over time, and with longstanding disease retain minimal secretion reflected by C-peptide levels greater than 2.0 ng/mL.

The are several important considerations in making the clinical diagnosis of T2D. First, the categories of normoglycemia, prediabetes, and mild diabetes based on fasting or 2-hour OGTT glucose values can vary in individual patients over time, and glycemic status should be confirmed by repeated testing on a separate day. Second, HbA1c has high specificity but relatively low sensitivity for diagnosing prediabetes or mild diabetes.[86] Clinicians should confirm glycemic status using fasting and/or 2-hour OGTT glucose rather than reliance on HbA1c alone. Third, with advancing age above 50 years of age, an increasing majority of patients will have prediabetes on the basis of elevated 2-hour OGTT alone,[87] and the diagnosis will be missed if an OGTT is not performed.

HbA1c levels reflect the average of the ambient blood glucose levels developed throughout each day for the preceding 3 months. This measurement has been adapted clinically as a reliable measure of successful glucose control during treatment for T1D and T2D. It is closely correlated to the development of retinopathy and other vascular complications due to elevated glycemic levels. Maintenance of HbA1c levels at 6.5% to 7.0% with no recurring hypoglycemia during treatment with oral agents or insulin is generally considered acceptable glycemic regulation (see Chapter 40). Levels between 7.0% and 8.0% are recommended for people recurrently at risk for hypoglycemia during treatment.

Overview of the Evolving Glucoregulatory Defect

Glucose homeostasis reflects a balance between insulin secretion and tissue insulin sensitivity in both the fed and fasted state. Hyperglycemia in most cases of T2D is a consequence of both impaired insulin secretion and insulin resistance.[88-90] There are four key tissues of particular significance in the development of abnormal glucose tolerance. They are the pancreas, liver, skeletal muscle, and adipose tissue, as illustrated in Fig. 33.2. Insulin resistance in liver and skeletal muscle contribute directly to the systemic manifestation of insulin resistance, namely hyperinsulinemia in the face on normo- or hyperglycemia. In insulin-resistant individuals, normal fasting glucose levels are maintained by compensatory increases in rates of insulin secretion that inhibit hepatic glucose output (HGO) in balance with counterregulatory hormones such as glucagon, glucocorticoids, and growth hormone that increase HGO. When fasting glucose levels become elevated in IFG and T2D, the HGO rate is increased, because insulin secretion is no longer sufficient to compensate for hepatic insulin resistance and is highly correlated with the severity of the fasting hyperglycemia. Elevated HGO rates are primarily the result of accelerated gluconeogenesis, which are facilitated by increased flux of gluconeogenic precursors and elevated free FAs (FFAs) and glucagon levels. The other key tissue contributing to insulin resistance is skeletal muscle, which is responsible for 70% to 80% of all insulin-mediated glucose uptake *in vivo*. Peripheral insulin resistance is largely due to insulin action defects in skeletal muscle that impair insulin's ability to stimulate glucose transport. Essentially all patients with CMD who progress to T2D exhibit a relative degree of insulin resistance in skeletal muscle.

Not all patients with CMD and prediabetes progress to overt T2D. Those patients who do develop T2D and frank hyperglycemia have defective pancreatic β cells that undergo exhaustion under conditions of the chronic metabolic stress of insulin resistance and continuous hyperglycemia. In some people with longer duration of diabetes, this leads to accelerated apoptosis and reduction in β cell mass. Thus, although causal mechanisms and clinical phenotypes can be heterogeneous in different T2D patient groups, the ultimate development of chronic hyperglycemia involves some combination of impaired insulin secretion, insulin resistance, and increased hepatic glucose production. The relative magnitude and contribution of these three metabolic abnormalities can vary depending upon specific subsets of inherited susceptibility genes, as well as other biological, behavioral, and/or environmental factors operative in individual patients or subgroups of patients. For example, T2D can develop in some lean people who do not clinically appear to have insulin resistance because they use only small amounts of insulin (e.g., 20 units/day), yet maintain acceptable levels of HbA1c.

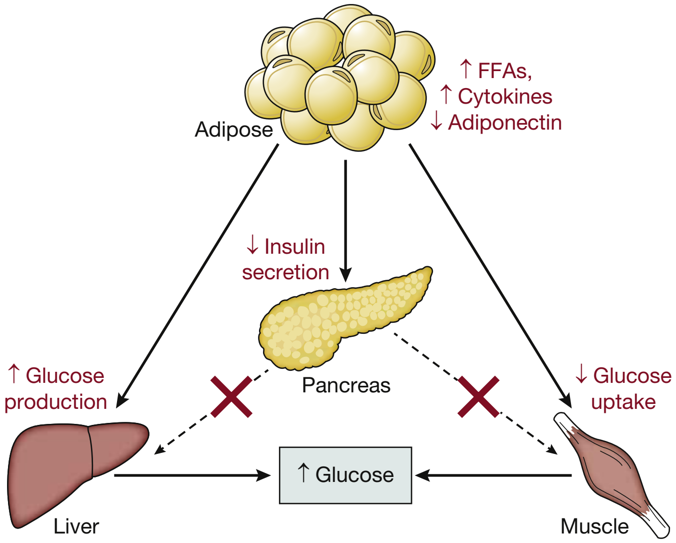

Fig. 33.3 Abnormalities in four key tissues contribute to hyperglycemia in type 2 diabetes. Dysfunctional and inflamed adipose tissue results in dysregulated secretion of adipocytokines and defects in fat storage, which leads to increased release of free fatty acids (FFAs) and ectopic accumulation of lipid in myocytes and hepatocytes. Insulin resistance develops in skeletal muscle with impaired stimulation of glucose uptake and in liver with decreased suppression of hepatic glucose output. A critical defect involves pancreatic β cell exhaustion with an inability to secrete sufficient insulin to compensate for insulin resistance in muscle and liver.

Adipose tissue is an additional tissue contributing to T2D pathogenesis and is increasingly thought to play a primary role in CMD and in the development of associated abnormalities in insulin secretion and action.[91] This tissue is a complex organ that is a central regulator of metabolism via the secretion of hormones and is also a depot for fuel storage as triglycerides and FA release to meet energy needs. In the insulin-resistant state, there is a relative redistribution of fat to the intraabdominal compartment, and adipose tissue contains increased numbers of inflammatory macrophages. Crossstalk involving factors from both adipocytes and macrophages result in dysregulated secretion of adipocytokines such as adiponectin, leptin, resistin, PAI-1, and proinflammatory cytokines.[92-95] Adipocytes themselves become insulin-resistant regarding stimulation of glucose transport, lipogenesis, and antilipolysis, and, as a consequence, dysfunctional triglyceride storage leads to increased release of FFAs. These factors can produce oxidative stress and inflammation in other tissues, a systemic clotting diathesis, and accumulation of intracellular fat that increases insulin resistance in muscle and liver and predisposes pancreatic β cells to secretory exhaustion. The superimposition of obesity further expands intraabdominal adipose tissue under these conditions and further worsens these pathophysiological processes. While adipocytes develop defects in insulin-stimulated glucose transport, the contribution of adipose tissue to total body glucose disposal is minor in comparison to muscle. Therefore, the adverse impact of dysfunctional adipose tissue on glucose homeostatic mechanisms occurs primarily through the abnormal secretion of adipocytokines and FFAs. Adipose tissue may also affect metabolism via additional mechanisms including the release of microsomes containing microRNAs that can influence gene expression in other tissues; local nerve fiber networks that can signal to the central nervous system (CNS), altering sympathetic tone; and release of other biofactors.[91]

In addition to abnormalities illustrated in Fig. 33.3, other defects and dysfunctional tissues contribute to the development of

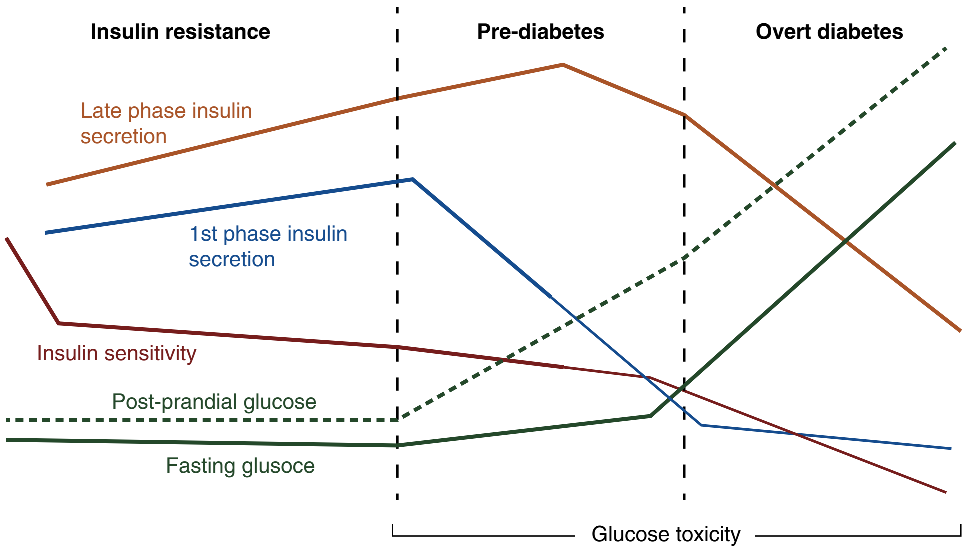

Fig. 33.4 The metabolic evolution of type 2 diabetes (T2D). The development of T2D begins with the insulin resistance phase, where increased first- and second-phase insulin secretion compensates for a decrease in insulin sensitivity in muscle and liver, sufficient to maintain normoglycemia. In the prediabetes phase, insulin secretion becomes inadequate to maintain normoglycemia. First-phase insulin secretion is abrogated, with a rise in postprandial glucoses followed by a decline in second-phase insulin secretion and the appearance of impaired fasting glucose. The diabetes phase features overt hyperglycemia accompanied by progressive β cell exhaustion. In both the prediabetes and diabetes phases, glucose toxicity at the level of the pancreatic β cell contributes to reductions in glucose-induced insulin secretion (also see Chapter 36).

hyperglycemia in T2D,[96] including: (i) increased glucagon secretion by pancreatic α cells, which augments hepatic glucose production[97]; (ii) decreased incretin production contributing to reduced insulin secretory responses[98]; (iii) increased reabsorption of filtered glucose in the renal proximal tubules[99]; (iv) altered neurotransmitter functions (e.g., dopamine) in the CNS affecting the sympathetic nervous system and circadian activities[100]; and (v) dysregulated interaction of satiety hormones acting on central feeding systems that augment caloric intake and cause obesity.[101]

Progression of Abnormal Glucose Tolerance

Metabolic Evolution of Type 2 Diabetes. Metabolic progression to overt T2D represents a continuous process but can be described in terms of transitions involving three pathophysiological phases.

Insulin Resistance Phase. The schematic in Fig. 33.4 illustrates the progression of changes in insulin secretion, insulin resistance, and glycemia towards overt diabetes. In most patients, the progression to abnormal glucose tolerance begins with insulin resistance,[89,102] although there are smaller subsets of lean patients in whom the defect in insulin secretion predominates, and insulin resistance is minimal or nonexistent. Relative differences in insulin sensitivity are evident in children, a trait that is inherited but is also impacted significantly by environmental factors, early life stress, and *in utero* exposures to maternal obesity, gestational diabetes, low birth weight, and other factors. In those individuals who are on the insulin-resistant side of the spectrum, pancreatic β cell secretion is increased over periods of time that can last well into adulthood, resulting in elevated circulating insulin and C-peptide levels. To the degree that hyperinsulinemia compensates for the prevailing degree of insulin resistance, normal values of fasting and postprandial glucose are maintained.[90] While hyperinsulinemia is sufficient to normalize HGO and muscle glucose uptake in the insulin resistance phase, pathophysiological processes inherent in the insulin resistance state are ongoing (see Natural History of Type 2 Diabetes as an End-Stage Manifestation of Cardiometabolic Disease section and Fig. 33.18). Therefore, these patients remain at increased risk for development of T2D, NAFLD, and CVD.

Prediabetes Phase. A subpopulation of patients will progress to prediabetes when insulin secretory responses become insufficient to compensate for progressive insulin resistance.[90] Patients with declining insulin secretion harbor a primary genetic predisposition to β cell exhaustion under the chronic stress of insulin resistance, as well as to the toxic effects of the insulin resistant state caused by elevated FFAs (lipotoxicity), chronically elevated glucose levels (glucotoxicity), oxidative stress, and inflammation (also see Chapter 36). The first detectable abnormality in prediabetes is a rise in postprandial glucose levels, which meet criteria for IGT. This is when the 2-hour glucose value during a 75-gram OGTT rises above the normal value of less than 140 mg/dL (<7.8 mmol/L) to 140 to 199 mg/dL (7.8–11.0 mmol/L). This is followed by IFG with rising fasting glucose values into the range of 100 to 125 mg/dL (6.9 mmol/L).

The most sensitive test for defective β cell function is the intravenous glucose tolerance test (IVGTT), which has been used to study the decline in insulin secretion and to differentiate and quantify early or first-phase and late, or second-phase, glucose-induced insulin secretion. First-phase insulin secretion is a sharp peak of rising then falling insulin levels from 3 to 5 minutes from the time of the glucose injection, while second-phase insulin secretion has a lower and more sustained elevation over baseline that generally lasts approximately 2 hours or more until normoglycemia is restored.[103,104]

Fig. 33.5 demonstrates the loss of first-phase and eventual decline in second-phase insulin secretion with the progressive rise in fasting plasma glucose. As patients progress to IFG, first-phase insulin secretion begins to decline and is completely lost as the fasting glucose rises above 115 mg/dL.[105] Second-phase insulin secretion is initially augmented above normal but then undergoes a progressive decline as fasting glucose values rise above 115 mg/dL. Defective first-phase insulin response is a specific abnormality relative to glucose as a secretagogue, because first-phase responses to nonglucose stimuli, such as isoproterenol, secretin, and arginine, remain intact in hyperglycemic patients[106-108]; Fig. 33.6). Thus, in this sense, the defect in glucose-stimulated first-phase insulin secretion mechanistically represents a problem with glucose sensing rather than a global secretory defect in β cells. This is further illustrated by impaired "glucose potentiation" of responses to nonglucose secretagogues. For example, the acute insulin response to intravenous arginine increases as the glucose concentration is experimentally raised. Investigators have plotted the increase in insulin response as a function of the increasing glucose level and quantified the slope of this relationship as the glucose potentiation slope.[109] This measure of β cell function is reduced in patients with T2D (the reader is referred to Chapter 29 for a full discussion of regulation of insulin, glucagon, and GLP-1 secretion).

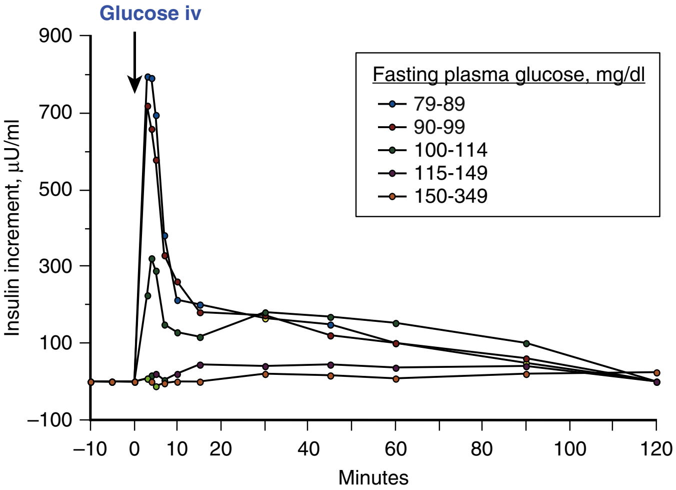

Fig. 33.5 **Intravenous glucose tolerance tests performed in subsets of patients with increasingly elevated fasting plasma glucose.** First-phase insulin secretion occurring 3–5 minutes after an intravenous (iv) glucose challenge is abrogated as fasting glucose levels rise from 90 to 115 mg/dL. Second-phase insulin secretion is initially augmented above normal but then undergoes a progressive decline as fasting glucose values rise above 115 mg/dL. (Data from Brunzell JD, Robertson RP, Lerner RL, et al. Relationships between fasting plasma glucose levels and insulin secretion during intravenous glucose tolerance tests. *J Clin Endocrinol Metab.* 1976;42:222–229.)

Diabetes Phase. With progressive deterioration, prediabetes transitions to diabetes as fasting glucose rises to greater than or equal to 126 mg/dL (greater than or equal to 7.0 mmol/L) and 2-hour OGTT glucose levels are greater than or equal to 200 mg/dL (greater than or equal to 11.1 mmol/L). This is associated with ongoing progressive deterioration of β cell function, with the further decline in second-phase insulin secretory responses often in relationship to the degree of hyperglycemia. There are also further increases in HGO. The continued worsening of these defects continues over the duration of T2D[110] and is responsible for progressive hyperglycemia and the ongoing need for intensification of diabetes treatments. Basal or fasting insulin levels may be normal or elevated in T2D; however, it is important to consider that patients are hyperglycemic. When nondiabetic people are made hyperglycemic by intravenous infusion of glucose, circulating insulin levels are much higher than those found in T2D,[109,111] indicative of the underlying impairment in insulin secretion.

Responses to Oral Glucose and Meals.

Fig. 33.7 illustrates the spectrum of glucose and insulin responses during OGTTs in groups of individuals with progressive glucose intolerance.[112] Normoglycemic individuals have the lowest glucose values and intermediate insulin levels. With progression to IGT, postingestion glucose levels are elevated despite being accompanied by the highest levels of insulin with a delay of the peak insulin response. However, once fasting glucose levels rise above normal in IFG, all glucose levels become more markedly increased, and insulin levels fall with a further delay in the insulin peak. The slower rise in insulin levels and delay in the peak response indicate that there is a defect in early-phase insulin secretion and more sluggish responses to glucose, analogous to the loss of first phase secretion with the IVGTT. Patients with diabetes have the highest level of hyperglycemia and profoundly diminished stimulated insulin levels, with minimal stimulation by oral glucose. The responses to mixed meals largely recapitulate the OGTT data, with one exception. While β cell responses to glucose are impaired, secretion stimulated by nonglucose secretagogues such as amino acids is preserved,[106-108] particularly in patients with mild or shorter-duration diabetes. These patients have more robust late-phase insulin responses to mixed meals from 2 to 4 hours after the meal, even if peak responses continue to be delayed, and the relative degree of glucose intolerance with mixed meals is less severe than that observed during OGTTs. In patients with longer

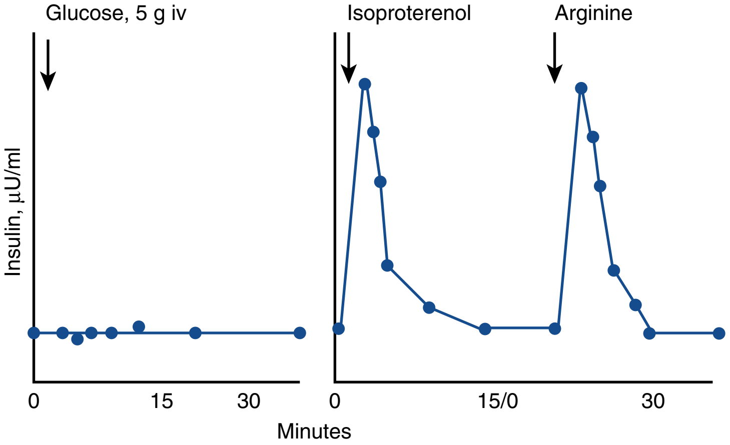

Fig. 33.6 **First-phase insulin secretory responses to glucose, isoproterenol, and arginine in patients with hyperglycemia.** First-phase secretion is absent in response to intravenous (iv) glucose but intact following administration of iv isoproterenol or arginine, indicating that there is a predominate defect in glucose sensing by the pancreatic β cell. (Data from Robertson RP, Porte Jr D. The glucose receptor. A defective mechanism in diabetes mellitus distinct from the beta adrenergic receptor. *J Clin Invest.* 1973;52:870–876.)

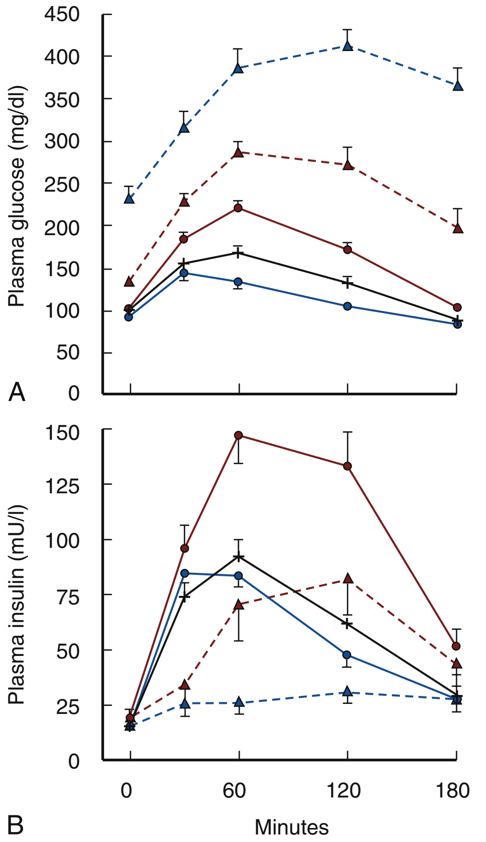

Fig. 33.7 **Glucose and insulin responses during oral glucose tolerance tests.** The data show mean ± standard error values for plasma glucose (**A**) and insulin (**B**) in normal controls *(blue circles)*, borderline glucose intolerance *(cross, black line)*, impaired glucose tolerance *(red circles)*, fasting hyperglycemia 110–150 mg/dL *(red triangles, broken line)*, and fasting hyperglycemia >150 mg/dL *(blue triangles, broken line)*. (Data from Reaven GM, Olefsky JM. Relationship between heterogeneity of insulin responses and insulin resistance in normal subjects. *Diabetologia*. 1977;13:201–206.)

duration of diabetes and more severe hyperglycemia, insulin responses to both mixed meals and glucose remain diminutive.

Progression of Prediabetes to Type 2 Diabetes. The proportion of patients with prediabetes (IFG, IGT, or both) who progress to T2D can vary depending on ethnicity, environmental factors, biological factors, and the methods of assessment. In the Diabetes Prevention Program, patients with IGT developed T2D at a rate of 10% per year.[113] In a metaanalysis, annualized incidence rates of diabetes were 4% to 6% for isolated IGT, 6% to 9% for isolated IFG, and 15% to 19% in those with combined IFG and IGT.[114] Over time, up to 70% of patients with prediabetes will progress to T2D, while others will remain with prediabetes or revert to normal glucose tolerance. The presence of metabolic syndrome and its composite traits also impact T2D risk. Risk of incident diabetes rises progressively over 40-fold from the lowest risk category comprised of obese individuals with no traits of metabolic syndrome, to isolated IFG or IGT, up to the highest risk in obese patients who meet criteria for both metabolic syndrome and prediabetes.[5] In this way, risk stratification can identify those at highest risk for application of more intensive interventions for diabetes prevention.

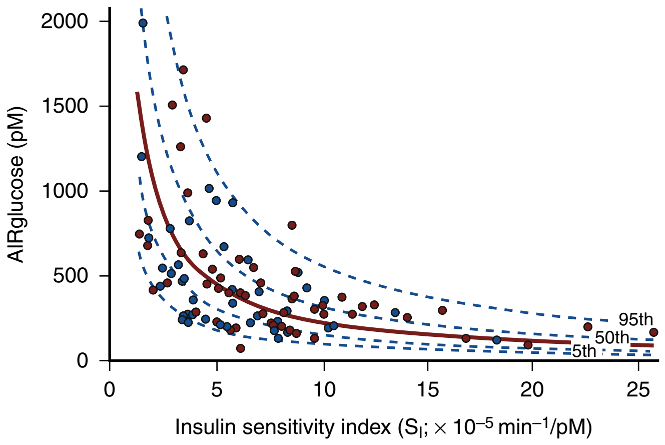

Fig. 33.8 **Relationship between insulin secretion and insulin sensitivity in healthy normoglycemic individuals: the disposition index.** The hyperbolic plot relates the acute insulin response (AIR) to intravenous glucose against the insulin sensitivity index and shows the best fit relationship (50th percentile) as the solid curve, and dashed curves for the 5th, 25th, 75th, and 95th percentiles. Normoglycemia is maintained, because changes in insulin sensitivity are balanced by a reciprocal and proportionate change in β cell function. (Data from Kahn SE, Prigeon RL, McCulloch DK, et al. Quantification of the relationship between insulin sensitivity and beta-cell function in human subjects: evidence for a hyperbolic function. *Diabetes*. 1993;42:1663–1672.)

Relationship Between Insulin Secretion and Insulin Resistance. There have been academic arguments about whether insulin resistance or impaired insulin secretion is the primary defect in T2D. Some investigators have contended that insulin resistance is primary, because insulin resistance occurs early and can predict the future development of T2D. However, this may constitute a false argument. Insulin resistance must be enjoined by impaired β cell secretion for the development of T2D, which does not occur in most obese or insulin-resistant individuals.[115] Rather, individuals who progress to diabetes are those who inherit subsets of susceptibility genes that adversely affect β cell function under the chronic stressor conditions of the insulin-resistant state. These latter patients fail to secrete sufficient insulin to maintain normoglycemia. This is best illustrated conceptually by the disposition index shown in Fig. 33.8. In normoglycemic individuals, the relationship between measures of β cell function and insulin sensitivity is hyperbolic as insulin secretion increases to match progressive declines in insulin sensitivity.[116-118] In patients with prediabetes or T2D, insulin secretion falls below that required to maintain normoglycemia at any level of insulin resistance. The product of the measures of insulin sensitivity and secretion is referred to as the disposition index, and low values that fall below the hyperbolic curve regardless of the degree of insulin resistance are required for development of hyperglycemia. The disposition index predicts progression to overt diabetes among insulin-resistant individuals[119] and has a high heritability index of 0.67.[120] The reduced compensatory capacity of the β cell in insulin-resistant patients with IGT is also manifest in patients undergoing graded glucose infusions. Patients with IGT secrete less insulin at each increasing level of induced hyperglycemia than do normoglycemic individuals matched for similar degrees of insulin resistance and obesity.[121]

In addition to diminished glucose-induced insulin secretion, there are other manifestations of abnormal β cell function under conditions of chronic stress from insulin resistance. First, the proportion of proinsulin that is secreted relative to insulin is increased in hyperinsulinemic states, perhaps reflecting incomplete processing of the proinsulin molecule prior to secretion.[90] Second, insulin secretion is normally characterized by ultradian oscillations occurring every 80 to 150 minutes, with superimposed rapid insulin pulses occurring every

Fig. 33.9 **The "two hit" formulation for the development of type 2 diabetes.** Both insulin resistance and impaired β cell function are required for the development of hyperglycemia.

5 to 15 minutes.[122] These pulses become less frequent and irregular in patients with T2D and in their nondiabetic relatives.[123,124] Finally, amylin is cosecreted with insulin from the β cell. In T2D, amylin can aggregate as amyloid fibrils in pancreatic islets, and accumulations of islet amyloid peptide (IAPP) are found in most patients with T2D at autopsy. While the clinical significance is controversial, IAPP is toxic to β cells *in vitro* and could contribute to a reduction in β cell mass via apoptosis.[125]

In summary, there are several salient observations regarding glucoregulatory abnormalities leading to T2D. First, the progression of abnormal glucose tolerance requires two basic defects, the presence of insulin resistance and the predisposition to β cell failure over time, consistent with the "two hit" formulation for diabetes pathogenesis (Fig. 33.9). If insulin secretion remains robust and sufficient to compensate for insulin resistance, then normoglycemia will be sustained. Second, the contribution of HGO in driving fasting glucose values to higher levels is critical for progressive hyperglycemia. Thirdly, diabetes is itself a progressive disease with further worsening of insulin resistance and deterioration of β cell secretory capacity, which is attributable in part to glucose toxicity and chronic oxidative stress[126] (see Fig. 36.5).

Reversibility of Defects in Insulin Secretion and Insulin Sensitivity in Type 2 Diabetes. Insulin resistance and impaired insulin secretion in T2D are at least partially reversible following an overnight infusion of insulin to lower glucose levels to the normoglycemic range[127] or a period (~2–3 weeks) of intensive therapy that produces normalization or near normalization of glycemia.[128] The improvements with intensive treatment are achieved whether euglycemia is achieved by insulin therapy, oral agents, or weight loss. The reversibility of defects in insulin secretion and sensitivity are consistent with the concept of glucose toxicity.[128-133] In poorly controlled T2D, restoration of euglycemia enhances β cell function primarily due to improved glucose sensing with restoration of insulin secretion. Regarding insulin resistance, exposure to high glucose decreases activity of the insulin-responsive glucose transport system both in cultured calls and *in vivo* in skeletal muscle, and these defects are reversible in a euglycemic environment. Therefore, in T2D, there are two components to overall insulin resistance; the first is the insulin resistance of CMD that may antedate the development of T2D, and the second is the additive effect of glucose toxicity that can be reversed by euglycemic therapy.[128]

Weight loss also leads to improvements in insulin secretion and sensitivity and can effectively be used to prevent progression to T2D in patients with metabolic syndrome or prediabetes, or to treat diabetes once the disease is present. In all instances, weight loss in T2D leads to better glycemic control with less need for diabetes medications. In the Look AHEAD Study, there were progressive improvements in HbA1c, fasting glucose, blood pressure, triglycerides, and high-density lipoprotein–cholesterol with increasing degrees of weight loss above 5%.[134] Substantial rates of diabetes remission have been observed with greater than or equal to 7% to 10% weight loss, whether achieved by lifestyle interventions including a very low calorie diet,[135] with obesity medications,[136] or following bariatric surgery.[137] Following bariatric surgery, the majority of patients with T2D require reductions or cessation of diabetes medications within days after surgery even before weight loss occurs. This is due to an increase in insulin sensitivity associated with marked reductions in intracellular lipid in muscle and liver, as has been observed within days of instituting a very low calorie diet.[138,139] Insulin secretion is also enhanced following surgery, and longevity of these improvements is the major determinant of the period of time T2D remains in remission (see Chapter 27 for further information about bariatric surgery for T2D).

KEY POINTS

- Four major tissues contribute to progression from normoglycemia, to prediabetes, to type 2 diabetes: impaired insulin-stimulated glucose uptake into skeletal muscle, impaired suppression of hepatic glucose output by insulin, diminished glucose-induced insulin secretion from the pancreas, and dysfunctional adipose tissue characterized by inflammation and abnormal release of adipocytokines and free fatty acids.

KEY POINTS

- The two essential causes of hyperglycemia in type 2 diabetes are islet β cell dysfunction and insulin resistance. First-phase insulin responses deteriorate when fasting glucose is greater than 100 mg/dL and disappear when it exceeds 115 mg/dL. Muscle, liver, and adipose tissue are the dominant sites for insulin resistance.

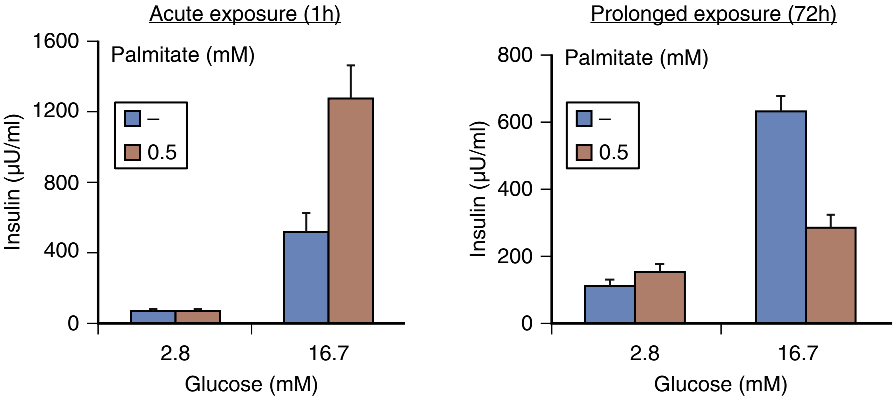

Fig. 33.10 **Effects of acute and chronic exposure to palmitate on glucose-induced insulin secretion in cultured β cells.** Acute (1 hour) exposure of cells to palmitate amplifies the insulin secretory response to glucose (16.7 mM), while chronic exposure (72 hours) impairs glucose-induced insulin secretion compared with controls. (Data from Briaud I, Harmon JS, Kelpe CL, et al. Lipotoxicity of the pancreatic beta-cell is associated with glucose-dependent esterification of fatty acids into neutral lipids. *Diabetes*. 2001;50:315–321.)

Remission of diabetes and its duration, as well as defects in insulin secretion and action, are greater in patients with shorter duration of diabetes (e.g., <5 years) as opposed to longer periods of sustained hyperglycemia (e.g., >10–15 years).[137] While mechanisms are not clear, it appears that the adverse effects of glucose toxicity and lipotoxicity become less reversible with time.

Mechanisms Causing Pancreatic β Cell Dysfunction

A general and essential focus for endocrinologists is to identify mechanisms of disease, which in turn paves the way to new therapies for treatment and prevention. However, because T2D is a clinical diagnosis based primarily on hyperglycemia and its secondary complications, it is not possible to develop a list of single mechanisms for T2D, with the exception of less common monogenic forms, such as patients with MODY (see Chapter 31). Nevertheless, glucose toxicity is an important consequence (not a cause) of chronic hyperglycemia that is responsible for oxidative damage in body tissues, including the pancreatic β cell. In the β cell, there are metabolic processes that normally form reactive oxygen species (ROS), which in physiologic concentrations are known to contribute to health in many ways, such as supporting gene transcription and killing dangerous bacteria. However, studies using *in vitro* islets and intact rodents have shown that excessive ROS concentrations in the pancreatic islet cause β cell apoptosis and adversely affect β cell replication.[140,141] The preferred metabolic pathway for metabolism of glucose is via the Krebs cycle and oxidative phosphorylation. However, when the β cell is presented with hyperglycemia, excessive glucose entry into the cell results in glucose catabolism via multiple alternative pathways in which ROS levels rise to deleterious levels. This is particularly dangerous for β cells because they do not contain the normal complement of endogenous antioxidant enzymes compared to other tissues (the reader is referred to Chapter 36 for a full discussion of the molecular mechanisms of β cell glucose toxicity and chronic oxidative stress).

Importantly, the dimension of time is highly essential to the development of glucotoxicity and lipotoxicity. While brief exposure of β cells *in vitro* to elevated concentrations of glucose or FFAs actually augment glucose-induced insulin secretion, it is only with prolonged exposure of β cells to glucose and FFA that deleterious effects on glucose-induced insulin secretion are seen[142] (Fig. 33.10). Prolonged, time-related exposure of β cells to glucose and FFAs is accompanied by elevated intracellular markers of ROS, which are mechanistic in causing cell damage and functional failure.[142] Such failure, however, is reversible if the high concentrations of glucose and FFA are removed. Unger originally popularized the term lipotoxicity,[144] and Prentki and Corkey[145] have proposed the term glucolipotoxicity to allow for the possibility that prolonged elevated glucose and lipid levels together account for deterioration of β cell function in T2D (Fig. 33.11). This relationship was examined in studies of Zucker diabetic fatty (ZDF) rats that develop hyperglycemia and hyperlipidemia when fed a high-fat diet[146] (Fig. 33.12). One group of animals was treated with bezafibrate to lower lipid levels, and another group was treated with phlorizin (a sodium-glucose cotransporter inhibitor) to lower glucose levels during ingestion of the high-fat diet. Adverse effects were assessed by measurements of β cell insulin mRNA levels. Phlorizin prevented the development of hyperglycemia and prevented the decrease in insulin mRNA levels. Bezafibrate prevented the elevation of lipid levels but did not prevent the decrease in insulin mRNA levels. Hence, in this animal model of T2D, the functional damage to the β cells caused by the high-fat diet were more likely to be due to glucose toxicity rather than lipotoxicity.

KEY POINTS

- As hyperglycemia becomes chronic, resultant glucose toxicity impacts the β cell via oxidative stress, causing defects in *PDX-1* and *MAFA* gene expression, which are required for normal insulin synthesis.

Studies have not been performed in humans to ascertain whether glucose toxicity, lipotoxicity, or a combination of the two is necessarily the dominant means by which hyperglycemia-induced ROS damages β cells. However, it is known that supraphysiological levels of blood glucose have adverse effects on the nuclear binding of two very important insulin gene regulatory proteins, Pdx-1 and MafA. These problems arise by a posttranscriptional defect in *PDX-1* gene expression[147] and a posttranslational defect in MafA gene expression[148] (see Chapter 36), as shown in β cell lines and *in vivo* in rodents. In other studies, it has been shown that β cells of ZDF rats undergo damage as a consequence of a very brief exposure to a high-fat diet. During this time blood glucose levels rise, as do β cell ROS concentrations. These adverse changes are accompanied by damage to β cell structure and function, which are recovered after discontinuation of the high-fat diet for 3 weeks when blood glucose levels return to normal.[149] This recovery is mediated by translocation of cytoplasmic inactive nuclear factor erythroid 2–related factor 2 (Nrf2) to the nucleus, where it then becomes activated

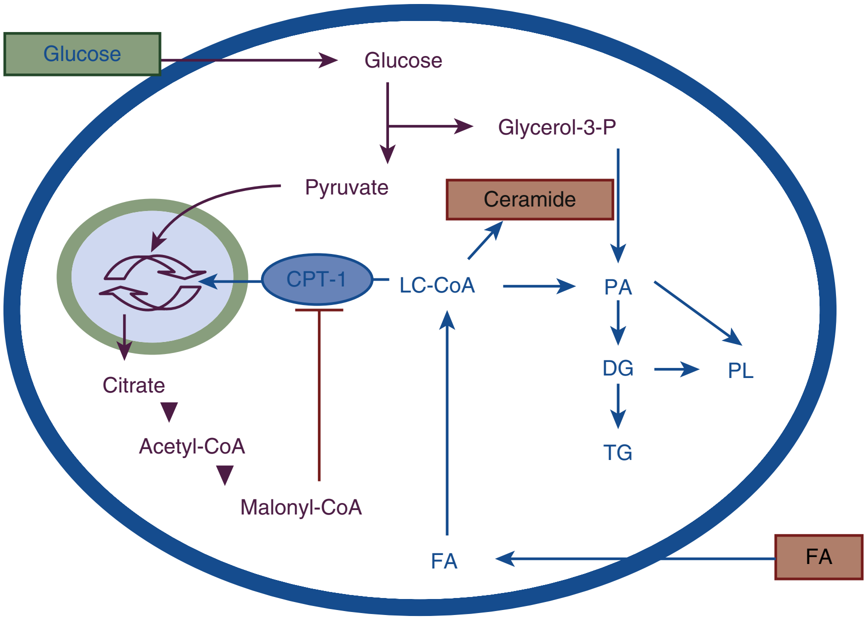

Fig. 33.11 **Potential mechanisms supporting the contention that the combination of elevated glucose and lipids ("glucolipotoxicity") accounts for β cell dysfunction in type 2 diabetes.** *PA*, Phosphatidic acid; *PL*, phospholipid; *DG*, diacylglycerol; *TG*, triacylglycerol; *FA*, fatty acid. Excessive metabolism of glucose leads to increased formation of malonyl CoA, which inhibits entry of long-chain fatty acids into the mitochondrion via carnitine palmitoyltransferase 1 (CPT-1) and subsequent oxidation. High circulating levels of long-chain fatty acids (LC) enter the cell; however, the LC-CoAs are unable to enter the mitochondrion, and instead lead to an increase in ceramide levels, which can cause formation of reactive oxygen species and oxidative stress. (Modified from Prentki M, Corkey BE. Are the beta-cell signaling molecules malonyl-CoA and cystolic long-chain acyl-CoA implicated in multiple tissue defects of obesity and NIDDM? *Diabetes*. 1996;45:273–283.)

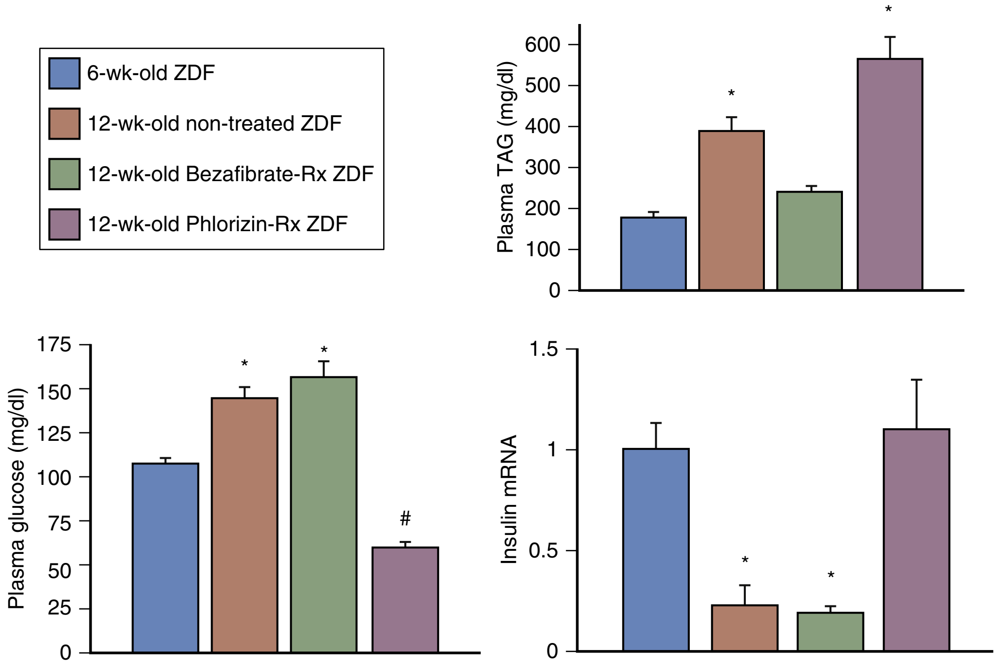

Fig. 33.12 **Effects of phlorizin and bezafibrate on plasma glucose, triglyceride levels, and insulin mRNA expression in β cells in Zucker diabetic fatty (ZDF) rats fed a high-fat diet.** The decline in insulin mRNA levels was only prevented when phlorizin was used to avoid hyperglycemia, not when bezafibrate was used to prevent the rise in plasma triacylglycerol (TAG) levels. The data are consistent with the conclusion that β cell injury is due to hyperglycemia (glucotoxicity) but not due to lipid elevations (lipotoxicity). (Data from Harmon JS, Gleason CE, Tanaka Y, et al. Antecedent hyperglycemia, not hyperlipidemia, is associated with increased islet triacylglycerol content and decreased insulin gene mRNA level in Zucker Diabetic Fatty rats. *Diabetes*. 2001;50:2481–2486.)

and stimulates production of hemoxygenase. Because no changes were seen in rates of apoptosis or cell proliferation throughout these studies, it was concluded that endogenous self-repair of oxidative damage by existing β cells via increased generation of endogenous antioxidants had occurred (see Chapter 36).

THE PATHOPHYSIOLOGY OF INSULIN RESISTANCE

Measurement of Insulin Sensitivity in Humans: Defect in Muscle Glucose Uptake

Insulin resistance is a trait that develops early in life, if not *in utero*. The interaction of genetic, epigenetic, environmental, and behavioral factors produces a wide range of individual variability in systemic insulin sensitivity. In research, the gold standard for measuring insulin sensitivity is the hyperinsulinemic euglycemic clamp. In this technique, an insulin infusion establishes steady-state hyperinsulinemia, and glucose is infused at a variable rate to maintain a target level of euglycemia. At high insulin levels when HGO is completely suppressed, the rate of glucose infusion equals the glucose disposal rate in tissues. At submaximal steady-state serum insulin concentrations, when HGO is not completely suppressed, it is necessary to coinfuse a glucose tracer (i.e., a radioactive or stable isotope–labeled glucose). Dilution of the tracer reflects the amount of unlabeled glucose being infused during the clamp plus the appearance of glucose from the liver. Subtraction of the known amount of infused glucose from the total glucose appearance calculated from dilution of tracer provides a measure of HGO. This allows investigators to calculate both the degree of hepatic suppression and total glucose uptake or disposal. The preponderance of glucose uptake under these conditions is into skeletal muscle, and, when normalized for the amount of lean body mass, is a measure of peripheral insulin sensitivity.

The clamp technique allows for the measurement of insulin sensitivity at multiple steady-state serum insulin concentrations and can be used to construct dose-response curves for insulin-mediated glucose uptake, as well as suppression of HGO. As shown in Fig. 33.13, patients with IGT have a glucose disposal curve that is shifted to the right without a pronounced decrease in the maximal response, in this study reflecting diminished sensitivity.[150] Patients with T2D have profound reductions in glucose uptake at all insulin concentrations, including a decrease in maximally stimulated glucose uptake indicative of a decrease in maximal responsiveness. The insulin resistance in patients with obesity and T2D is only slightly worse than that observed in lean patients with diabetes. This same approach for assessing the dose-response of insulin action can be employed before and after intensive therapy to illustrate reversibility of insulin resistance following a period of euglycemic therapy. In Fig. 33.14, patients with T2D were studied using multiple insulin dose clamps in the untreated state, managed with intensive insulin therapy by continuous subcutaneous infusion for 3 weeks, withdrawn from treatment, and then restudied.[128] The period of euglycemia resulted in marked increments in both sensitivity (shift to the right of the dose-response curve) and maximal insulin responsiveness, although patients did not achieve the higher glucose uptake rates observed in normoglycemic controls.

Insulin sensitivity as measured by hyperinsulinemic clamps varies by over 5-fold among individuals without diabetes.[25] Those individuals at the more insulin-resistant range of the spectrum will preferentially develop other properties of the insulin-resistant state and CMD (see Natural History of Type 2 Diabetes as an End-Stage Manifestation of Cardiometabolic Disease section and Fig. 33.18) and are at increased risk of progressing to T2D. Obesity is not necessary or sufficient as a cause of diabetes, as lean individuals develop T2D, and other patients with obesity are insulin-sensitive and not at increased risk of CMD

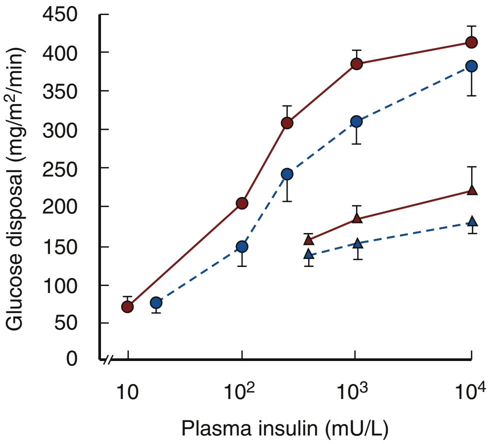

Fig. 33.13 **Dose-response curves for insulin-stimulated glucose disposal using the hyperinsulinemic euglycemic clamp method.** Mean values of glucose disposal or uptake rates expressed as mg glucose per meter squared body surface area per minute are shown at increasing steady-state serum insulin levels. The group with impaired glucose tolerance *(blue circles)* has a rightward shift in the dose-response curve (i.e., decreased sensitivity) compared with controls *(red circles)*. Lean *(red triangles)* and obese *(blue triangles)* patients with type 2 diabetes have both a rightward shift and a reduction in the maximal insulin response (i.e., decreased sensitivity and responsiveness). (Data from Kolterman OG, Gray RS, Griffin J, et al. Receptor and post-receptor defects contribute to the insulin resistance in noninsulin-dependent diabetes mellitus, *J Clin Invest.* 1981;68:957–969.)

(i.e., the metabolically healthy obese).[5] However, obesity and overweight can worsen insulin resistance and are present in the majority of patients with T2D.

Other methods for quantifying insulin sensitivity in humans include the insulin tolerance test, where a fixed amount of insulin is infused, and the rate of decline in plasma glucose is assessed as a measure of insulin sensitivity. Bergman and colleagues have modeled plasma glucose and insulin levels during an intravenous glucose tolerance test to generate an index of insulin sensitivity referred to as the minimal model.[151] Another method involves the suppression of endogenous insulin secretion using somatostatin followed by fixed rate infusions of insulin and glucose.[152] In this scenario, the steady-state plasma glucose concentration reflects the action of insulin at the serum level generated by the insulin infusion, and is used as a measure of *in vivo* insulin sensitivity. All these methods represent research methodologies and are not feasibly performed in clinical practice. To address this need, investigators have established various indices based on ambient glucose and insulin levels either under fasting conditions, such as the homeostatic model assessment,[153] or during an OGTT. However, these indices are variably predictive of clamp measurements of insulin sensitivity due to the fact that there are multiple physiological and pathophysiological determinants of circulating glucose and insulin independent of insulin sensitivity.[154] The development of metabolic syndrome traits as a clinical manifestation of the insulin-resistant state is perhaps the most immediate way to detect the present of insulin resistance in the clinic. Approaches such as CMD staging, which is based on the presence and severity of metabolic syndrome traits, can be used to quantify diabetes risk and is proportional to the degree of insulin resistance.[5,155]

Glucose Transport, Oxidative Metabolism, and Nonoxidative Metabolism

The reduction in insulin-stimulated glucose uptake into muscle during hyperinsulinemic clamp studies could be due to defects in glucose

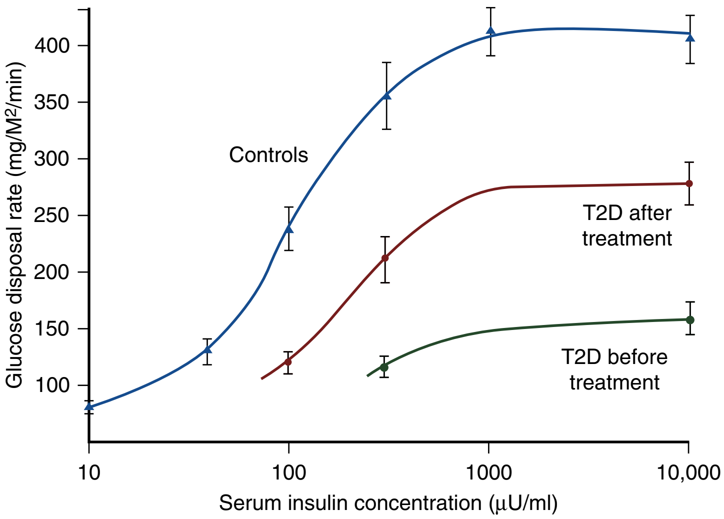

Fig. 33.14 **Insulin dose-response curves for stimulation of glucose disposal in normoglycemic controls and patients with type 2 diabetes (T2D) before and after intense euglycemic therapy.** Patients with T2D were studied in the untreated state and after a 3-week period of intensive glycemic control achieved using continuous subcutaneous inulin infusion. Euglycemic clamp procedures were used as described for Fig. 33.13. Insulin resistance in the untreated patients with T2D, manifested as a rightward shift in the dose-response curve and a decrease in maximal responsiveness, was partially reversed by the period of euglycemic therapy; however, patients did not achieve the degree of insulin sensitivity observed in lean controls. (Data from Garvey WT, Olefsky JM, Griffin RF, et al. The effect of insulin treatment on insulin secretion and insulin action in Type II diabetes mellitus. *Diabetes*. 1985;34:222–234.)

transport, formation of glucose-6P by hexokinase, or subsequent intracellular glucose metabolism. In cultured muscle cells and adipocytes, the glucose transport step is rate-limiting for overall insulin-stimulated glucose uptake and metabolism, and the same appears to be true for skeletal muscle *in vivo*. Investigators have used nuclear magnetic resonance spectroscopy to quantify intracellular glucose-6P[156] and biochemical methods to measure intracellular free glucose in muscle, and found both to be low under conditions of high glucose flux into muscle during hyperinsulinemic euglycemic clamp studies. This demonstrated that reduced stimulation of muscle glucose transport is directly responsible for lower glucose uptake rates and insulin resistance, as opposed to intracellular defects in glucose metabolism causing accumulation of unmetabolized glucose or glucose-6P. Nevertheless, defects in cellular glucose metabolism are also present in human insulin resistance.

KEY POINTS

- Skeletal muscle accounts for ~80% of insulin-mediated glucose uptake *in vivo*, and impaired stimulation of glucose transport into muscle is the predominant defect responsible for peripheral insulin resistance.

Once phosphorylated within the cell, glucose can be metabolized to glycogen for storage (i.e., nonoxidative metabolism) or undergo oxidation (i.e., oxidative metabolism). During clamp studies, the application of indirect calorimetry can assess the amount of glucose being oxidized, and nonoxidative glucose metabolism calculated as total glucose uptake minus oxidized glucose. Insulin's ability to stimulate glycogen synthase (GS), which is essential for nonoxidative glucose metabolism as well as oxidative metabolism, are both impaired in human insulin resistance.[157] In skeletal muscle during clamp studies the reductions in nonoxidative metabolism and rates of glycogen formation are explained by reduced glucose-6P availability as a result of the reduction in glucose transport, while the rate of insulin-stimulated glucose oxidation is impaired beyond that attributable to reduced glucose uptake. However, nonoxidative metabolism to glycogen accounts for the greater component of glucose disposal,[158] and the smaller contribution of oxidative metabolism does not impact overall rates of glucose uptake beyond that attributable to the transport defect. From this perspective, reduced rates of insulin-stimulated glucose transport into muscle are fundamentally responsible for insulin resistance.

Hepatic Insulin Resistance

The liver plays a key role in glucose homeostasis by releasing glucose derived from glycogenolysis or gluconeogenesis into the hepatic vein and out to the systemic circulation. Hepatic glucose production is fueled by uptake of FFAs, gluconeogenic substrates, and carbohydrates from the portal vein and hepatic artery. After an overnight fast, 90% of glucose released into the circulation comes from the liver, which is critical for maintaining euglycemia and energy required by the brain and other organs. After ingestion of carbohydrates, HGO falls rapidly, primarily due to the suppressive effects of insulin, and this helps limit the postprandial rise in plasma glucose levels. However, following the digestion and absorption of nutrients, glucose production is restored to meet systemic needs for glucose as insulin levels fall, and driven by the actions of counterregulatory hormones, the most important being glucagon, but also includin epinephrine, cortisol, and growth hormone.

The rate of hepatic glucose production after an overnight fast is increased in patients with IFG and T2D and is highly correlated with the elevation in fasting glucose levels. Fig. 33.15 shows correlation between fasting glucose and HGO in patients with T2D in the untreated state and after 3 weeks of euglycemic therapy achieved by continuous subcutaneous insulin infusion.[128] It is clear that, under fasting conditions, hepatic glucose production is a powerful determinant of the degree of fasting hyperglycemia. A second point is that elevated HGO rates are reduced following intensive treatment, and the reversal of this defect provides for the maintenance of lower fasting glucose levels following a period of euglycemia.

The increments in HGO are enabled by enhanced rates of gluconeogenesis, which in turn is driven by several pathophysiological processes in

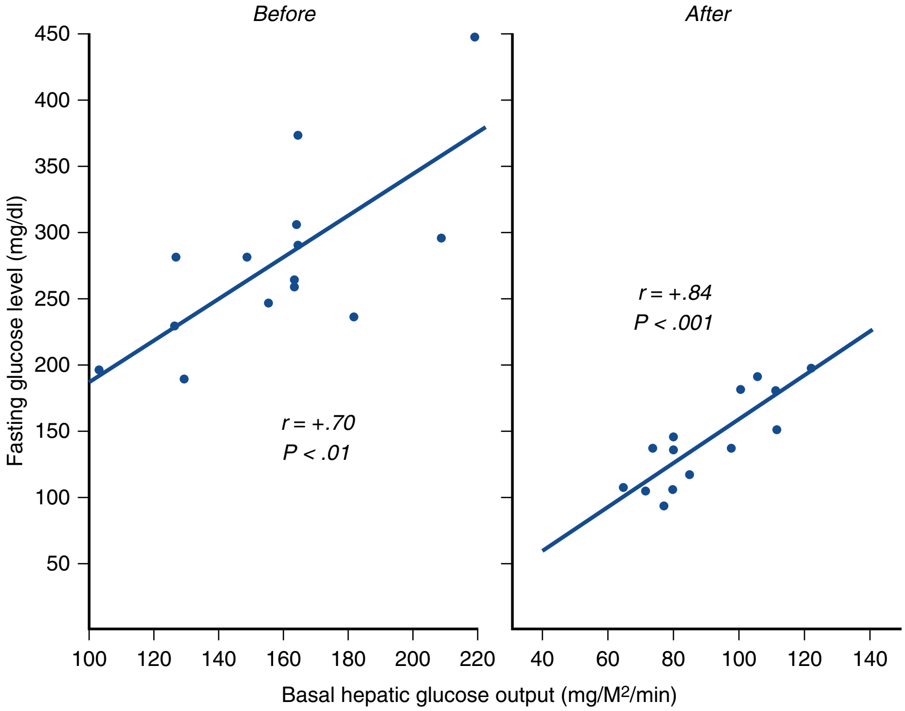

Fig. 33.15 The relationship between fasting glucose levels and basal hepatic glucose output rates in patients with type 2 diabetes (T2D) before and after euglycemic therapy. Patients with T2D were studied in the untreated state and after a 3-week period of intensive glycemic control achieved using continuous subcutaneous inulin infusion. Hepatic glucose output rates are expressed as mg glucose per meter squared body surface area per minute and were determined based on the dilution of an infused glucose tracer. Hepatic glucose production was highly correlated with the high glucose values in untreated patients and the lower glucose values after treatment. (Data from Garvey WT, Olefsky JM, Griffin RF, et al. The effect of insulin treatment on insulin secretion and insulin action in Type II diabetes mellitus. *Diabetes*. 1985;34:222–234.)

diabetes. First, glucagon levels are increased in T2D.[97] Glucagon release from pancreatic α cells is normally suppressed by rising glucose levels, and the presence of hyperglucagonemia in the face of hyperglycemia is indicative of α cell resistance to the inhibitory effects of glucose.[159] The importance of elevated glucagon in T2D is underscored by the observation that inhibition of glucagon secretion by infusion of somatostatin lowers hepatic glucose production and fasting glucose levels. Second, elevated plasma FFA levels, due to the impaired antilipolytic action of insulin in adipose tissue, provide an energy source that helps promote gluconeogenesis. Third, increased flux of gluconeogenic substrates to the liver, including alanine, lactate, and glycerol, act to sustain ongoing high rates of gluconeogenesis. Perhaps the most important cause of increased HGO in T2D is hepatic insulin resistance. In normal individuals, the effective dose for half-maximal suppression (ED50) of HGO is lower (~26 μU/mL) than for stimulation of peripheral glucose uptake (~58 μU/mL).[160] In T2D, the insulin dose-response curve for hepatic suppression is shifted to the right, with an approximately 2-fold increase in the ED50, while hepatic glucose production can still be completely suppressed at higher serum insulin concentrations. This reduction in hepatic insulin sensitivity further promotes the overall increase in glucose production in patients with T2D.

An addition hepatic defect contributes to hyperglycemia in T2D involving uptake of glucose from the portal vein. While skeletal muscle is quantitatively the most important tissue for disposal of an oral glucose load, approximately 20% to 25% of oral glucose is taken up by the liver.[161] Unlike muscle, where insulin directly stimulates glucose transport into the tissue, insulin plays only a permissive role in promoting hepatic glucose uptake. The main determinant of glucose transport into and out of the liver is the glucose concentration gradient between sinusoids and hepatocytes,[162] and reduced expression of hepatic glucose kinase may impair intracellular glucose trapping and glucose flux across this differential.[163] In T2D, uptake of glucose by the liver is impaired, and this contributes to postprandial hyperglycemia.[164]

In summary, in T2D the liver overproduces glucose in the basal state. This is an important cause of fasting hyperglycemia and indicates that the therapeutic suppression of hepatic glucose production is critical for achieving glucose control. High glucose output rates are due to accelerated gluconeogenesis, which is enabled by multiple properties of the diabetic state, including elevated glucagon and FFA levels, increased flux of gluconeogenic substrates to the liver, and a decrease in insulin sensitivity with respect to suppressing hepatic glucose production. Additionally, hepatic glucose uptake is impaired, and this contributes to postprandial hyperglycemia.

KEY POINTS

- Hepatic glucose output rates are elevated in type 2 diabetes and are highly correlated with the degree of fasting hyperglycemia. Increased glucose production is a consequence of hepatic insulin resistance and an inability to suppress augmented rates of gluconeogenesis.

THE MOLECULAR BASIS OF HUMAN INSULIN RESISTANCE IN TARGET TISSUES

General Principles

As a backdrop to discussing molecular events causing insulin resistance, the reader is referred to Chapter 30 for a discussion of general aspects of normal insulin action.

The figure shows normal insulin signal transduction in blue from the insulin receptor to activation of Akt and specific biological effector systems in target tissues. Molecules causing insulin resistance are indicated in filled red rectangles, together with environmental influences and processes that promulgate these defects.

Insulin resistance is central to the pathophysiology of T2D and CMD.[165] This term could apply to any of insulin's pleiotropic effects involving substrate metabolism, gene expression, ion flux, vasoregulation, and growth and differentiation. In this context, it applies to abnormalities causing the glucoregulatory defects leading to T2D, in particular molecular events impairing insulin's ability to stimulate glucose uptake and metabolism, reduce hepatic glucose production, and inhibit lipolysis. Approximately 80% of systemic insulin-mediated glucose uptake occurs in skeletal muscle, and insulin resistance at the level of muscle has been demonstrated in T2D using forearm and leg perfusion studies.[166,167] Investigators using *in vivo* techniques such as hyperinsulinemic clamps have demonstrated that systemic measurements of insulin resistance are correlated with reductions in insulin-stimulated glucose transport assessed in fat and muscle tissues removed from insulin-resistant subjects and studied *ex vivo.*[168] The conclusion is that systemic insulin resistance is due to insulin action defects at the level of target cells.

Once insulin enters tissues and arrives at the cell surface, insulin resistance could occur due to defects involving the insulin receptor, signal transduction, or effector systems that mediate insulin's biological effects. These biological processes can mediate normal dynamic functioning of insulin action as organisms adapt to changing physiological conditions, or, when unbalanced, can lead to pathophysiological consequences and the development of insulin resistance. In T2D, there is not one single lesion that predominates as a general cause of insulin resistance. Rather, there is an extensive array of mechanisms that dampen or inhibit signal transduction and impair the biological activity of effector systems, as illustrated in Fig. 33.16. Thus, variable but overlapping subsets of processes and susceptibility genes operate in individual patients to impair insulin action in a manner that contributes to the heterogeneity of T2D.

Insulin Resistance at the Level of the Insulin Receptor

Downregulation of Insulin Receptor Number. The first critical step in insulin signaling is binding of the hormone to cell surface receptors. In most patients with insulin resistance, including T2D and obesity, insulin target cells are observed to have fewer numbers of cell surface insulin receptors. Insulin receptor downregulation can be attributed to chronic exposure to high insulin concentrations, because this increases ligand-mediated internalization of receptors followed by lysosomal degradation, as well as diminished gene expression. The resulting decrement in cell surface insulin receptors without a change in binding affinity has been observed in isolated adipocytes, hepatocytes, and skeletal muscle from patients with obesity and T2D.[169,170] The decrease in receptor number did not approach the minimum complement of 10% to 20% of receptors needed to obtain maximal insulin responses. As a consequence, there remained "spare" receptors for maximal insulin action even after receptor downregulation. In this scenario, receptor downregulation results in a rightward shift of the insulin dose response curve, with decreased effects at submaximal insulin concentrations (e.g., the ED50), while maintenance of maximally stimulated responses is preserved. A decrease in maximal responsiveness would need to be attributed to a post–insulin binding defect, which was also observed in cells from these patients, indicative of downstream defects in insulin action.

Modulators of Insulin Receptor Function. Plasma differentiation factor 1 (PC-1), also referred to as ectonucleotide pyrophosphatase phosphodiesterase 1 (ENPP1), is a membrane glycoprotein with pyrophosphatase activity that appears to act as an intrinsic inhibitor of the insulin receptor tyrosine kinase. PC-1 has been shown to bind to the receptor and prevent the conformational change in receptor β subunits required for insulin binding. Muscle expression of PC-1 is elevated in diabetic patients and in obesity, and it correlates with diminished insulin receptor tyrosine phosphorylation and muscle glucose uptake.[171] Growth factor receptor–bound proteins (Grb10 and Grb14) can also bind the insulin receptor on phosphotyrosine residues, alter receptor tyrosine kinase activity, and disrupt receptor signaling.[172] The physiological role of Grb proteins in humans has not been fully clarified.

Insulin Resistance at the Level of Signal Transduction

Serine-Threonine Phosphorylation of Insulin Receptors and Receptor Substrate

Proteins. In target tissues obtained from patients with T2D, there is a reduction in insulin receptor tyrosine kinase activity and signaling through insulin receptor substrate docking proteins (e.g., IRS-1).[173,174] To probe a causal relationship with human insulin resistance, investigators have studied perturbations that either enhance or diminish *in vivo* insulin sensitivity to determine if there were commensurate changes in phosphorylation/dephosphorylation of the insulin receptor and IRS-1. Using muscle biopsies and euglycemic clamps, investigators have shown beneficial effects of treatment with thiazolidinediones,[175] exercise,[176] caloric restriction,[177] and tight glucose control.[178] In contrast, insulin resistance induced by infusion of a triglyceride emulsion worsened both insulin sensitivity and signaling defects.[170]

Reductions in the activity of the insulin receptor tyrosine kinase and IRS docking proteins is due in large part to serine-threonine phosphorylation of these proteins, which constitutes a major mechanism for negative modulation of insulin signal transduction. Serine phosphorylation diminishes insulin receptor tyrosine kinase activity and decreases receptor–IRS coupling by inhibiting insulin-mediated tyrosine phosphorylation of IRS-1, which is required for subsequent binding and activation of PI-3 kinase and stimulation of glucose transport.[180-183] There are consensus sequences in IRS-1 that make it susceptible to a wide variety of serine-threonine kinases. Several of these kinases have been shown to function as physiological modulators, causing desensitization of insulin signaling pathways under conditions of nutrient excess, inflammation, and cell stress responses. A second abnormality applies to the cell content of IRS-1, which can be diminished due to increased proteasomal degradation. Even so, the defect in tyrosine phosphorylation predominates in impaired signaling through IRS-1 to the degree that the decrease in IRS-1 protein may not be physiologically relevant. Key serine-threonine kinases participating in human insulin resistance include:

Protein Kinase C. PKCs are serine-threonine kinases that can phosphorylate IRS-1 and impair its ability to associate with the insulin receptor and with PI-3 kinase, resulting in desensitization of the PI-3 kinase pathway.[181,183-185] Hyperinsulinemia, hyperglycemia, and elevated circulating FFAs (e.g., nutrient excess) leads to increased intracellular diacylglycerol (DAG), which in turn activates conventional and novel PKC isoforms (e.g., PKCθ), principally via recruitment to the plasma membrane. In addition, insulin activates atypical PKCs, such as PKCζ, via the PI-3 kinase pathway, which is also capable of phosphorylating and impairing IRS function.[186]

Tumor necrosis factor-α (TNFα). TNFα is a cytokine produced by immune cells and also by adipocytes and muscle tissue that can mediate serine phosphorylation of IRS-1. TNFα expression is increased in adipose and muscle tissues as a function of insulin resistance, where TNFα appears to operate largely as an autocrine/paracrine factor.[187,188] In adipose tissue, TNFα and other proinflammatory cytokines are produced by adipocytes and macrophages under conditions of obesity and insulin resistance. TNFα activates other pathways that directly mediate increased serine phosphorylation of IRS-1, including PKC isoforms, the stress-induced kinase JNK, and IKKβ.[189-191]

JNK. JNK isoform proteins belong to the extended family of MAPKs and control many cellular functions through regulation of activator protein-1 (AP-1). Insulin has also been shown to activate JNK1 and JNK2, which then display increased serine kinase activity against multiple intracellular substrates, including IRS-1, IRS-2, and Shc.[192] In this way, JNK represents a negative feedback mechanism by which insulin inhibits its own signaling. However, JNK activity is also augmented during cellular stress responses, such as endoplasmic reticulum (ER) stress, and has been found to be increased in insulin-resistant states.[193]

NF-κB. NF-κB is a transcription factor that functions as a proinflammatory "master switch" during inflammation, upregulating the transcription of a wide range of inflammatory mediators.[194] NF-κB is normally retained in the cytoplasm by binding to members of the inhibitor of κB (IκB) protein family. During inflammatory or metabolic stress, NF-κB is activated by the IκB kinase (IKK) complex, which consists of two catalytic subunits, IKKα and IKKβ, and a regulatory subunit, IKKγ. The IKKβ subunit phosphorylates IκB, resulting in its ubiquitination and subsequent proteasomal degradation and in the release of NF-κB. The free NFκB is then able to translocate into the nucleus and activate the transcription of over 100 genes, most of which are proinflammatory.[195] Activation of NF-κB has been shown to accompany insulin resistance following high-fat feeding, in obesity, and in the metabolic syndrome.[196,197] Proinflammatory cytokines such as TNFα and IL-6 can also activate NF-κB. Weight loss, caloric restriction, and exercise training can lead to a reduction in transcription of the proinflammatory genes regulated by NF-κB. Drugs with antiinflammatory properties, such as thiazolidinediones, statins, and salicylates, can inhibit proinflammatory cytokine secretion by interfering with the NF-κB pathway.

IκB kinase-β (IKKβ). In addition to activating NF-κB, IKKβ is a serine kinase that has the ability to directly desensitize insulin signaling through serine phosphorylation of IRS or the insulin receptor.[194,198] The ability of TNFα to desensitize insulin action as a consequence of IRS serine phosphorylation may in part be mediated through IKKβ. An important biological effect of salicylates is the inhibition of the IKKβ, and treatment with high doses of salicylates improves glucose tolerance and enhances insulin sensitivity and secretion in human and rodents.[199-201]

Additional Factors that Inhibit Signaling by Affecting Tyrosine Phosphorylation. Endogenous phosphotyrosine phosphatases (PTPase) are able to dephosphorylate tyrosine residues on the insulin receptor β subunit and IRS docking molecules, resulting in a dampening of insulin signal transduction. Membrane-associated PTPase activity is increased in skeletal muscle from patients with T2D,[202] principally due to increments in cytosolic PTPase-1B and membrane-associated leukocyte antigen-related phosphatase.[203,204]

The suppressor of cytokine signaling-3 (SOCS) family of proteins was originally described as a negative feedback loop for cytokine receptors involving Janus kinase (JaK). The ability of cytokines and growth factors to augment expression of SOCS genes (*CIS* and *SOCS1–7*) via the JaK and signal transducer and activator of transcription (STAT) pathway is described in Chapter 30. SOCS1, SOCS3, and SOCS6 can bind to the C-terminus of the insulin receptor β subunit and block interaction between the insulin receptor and IRS.[204-207] Several factors that induce cellular insulin resistance also induce SOCS3 expression, including TNFα, growth hormone, and leptin.

Mechanisms Causing Downstream Signaling Defects. The reduction in IRS-1 tyrosine phosphorylation decreases the ability of the PI-3 kinase regulatory subunit to bind IRS-1, thus preventing activation of the PI-3 kinase catalytic subunit. Accordingly, insulin-stimulated PI-3 kinase activity in skeletal muscle is reduced in both obesity and T2D in a manner that correlates with the decrease in whole-body glucose disposal. PI-3 kinase acts to increase production of PI(3,4,5)P_3 and the downstream activation of PDK1 and Akt. The phosphatase and tensin homolog (PTEN) can dephosphorylate PI(3,4,5)P_3 on the 3 position, and SH2-containing inositol phosphatases (SHIPs) can dephosphorylate PI(3,4,5)P_3 on the 5 position of the inositol ring; in either instance, the ability of PI(3,4,5)P_3 to stimulate PDK1 is lost. Therefore, PTEN and SHIP can exert negative regulatory influences on insulin signaling with respect to its metabolic actions.[208] The degree to which these phosphatases play a role in human insulin resistance has yet to be fully defined.

The Tribbles (TRB) gene family in mammals is comprised of three proteins that have a truncated kinase domain lacking an adenosine triphosphate (ATP) binding site. Accordingly, TRBs are "psuedokinases" that lack detectable kinase activity but can bind to kinase substrates in phosphorylation cascades and inhibit their phosphorylation. TRB proteins, for example, can bind to Akt/PKB and inhibit its phosphorylation and activation in response to insulin,[209] while downregulation of TRB3 improves insulin sensitivity.[210] TRB3 is a glucose-responsive gene that is upregulated in human muscle as a function of rising glycemia. Importantly, it may mediate glucose-induced insulin resistance ("glucose toxicity") under conditions of sustained hyperglycemia.[211-213]

Insulin Resistance at the Level of Biological Effector Systems

Insulin regulates whole-body fuel homeostasis via specific effects in multiple target tissues. The nature of these biological actions varies dramatically from tissue to tissue, and these variations, for the most part, are not due to differences in insulin signal transmission (described earlier). Rather, tissue-specific insulin effects are principally explained by effector systems that are uniquely expressed in skeletal muscle, adipose tissue, and liver.

Insulin Effector System Defects in Skeletal Muscle. Skeletal muscle accounts for the bulk of insulin-stimulated glucose uptake *in vivo*,[166] and the hallmark of insulin resistance in humans is the impaired ability of insulin to stimulate the glucose transport effector system in skeletal muscle.[214] The major transporter isoforms that mediate glucose transport in cells with an insulin-responsive glucose transport system are GLUT1 and GLUT4. In unstimulated cells, GLUT1 predominates at the cell surface and facilitates glucose diffusion across the plasma membrane into the cytosol, where glucose is rapidly phosphorylated by hexokinase and metabolized. In contrast, over 90% of GLUT4 resides in intracellular vesicles in the basal state. The mechanism by which insulin augments glucose transport activity is by recruiting intracellular GLUT4 vesicles to the plasma membrane, followed by fusion and exposure of the glucose pore to the exofacial surface of the plasma membrane. The process of insulin-mediated GLUT4 translocation is described in Chapter 30.

In lean and obese patients with T2D or metabolic syndrome, insulin's ability to stimulate glucose transport into muscle is impaired due to a decrease in the cell surface appearance of GLUT4 following insulin stimulation.[214] Such an abnormality could be due to either impaired insulin signaling or defects intrinsic to the glucose transport effector system, and, in fact, both abnormalities are operative. Insulin signaling through the receptor/IRS/PI-3 kinase pathway is defective in human muscle. Activation of Akt is downstream of PI-3 kinase, and the data addressing whether Akt phosphorylation is defective in muscle from T2D patients are controversial.[215] Different authors report normal or decreased Akt activation or reduced activation at high, but not low, insulin concentrations, and the role of Akt is further complicated by the fact that only a small fraction of Akt phosphorylation is needed for maximal stimulation of glucose transport.[216] PKC isoforms, in particular PKCλ, are also downstream of PI-3 kinase and upstream of glucose transport stimulation, and there are reports of defects in cellular content and subcellular distribution of atypical PKC isoforms in T2D.[217,218] In any event, downstream insulin-stimulated phosphorylation of AS160 (TBC1D4) and TBC1D1 is impaired, and these Rab GTPase-activating proteins are final or near-final steps in insulin signaling and most proximal to engagement of the glucose transport effector system.[219]

Defects intrinsic to the glucose transport system have also been shown to be an important cause of insulin resistance in muscle and fat tissues from insulin-resistant and diabetic patients. Cellular depletion of GLUT4 transporters is a major mechanism of insulin resistance in adipocytes in obesity and T2D,[220] while GLUT4 expression is relatively normal in skeletal muscle.[221] However, in both muscle and fat, GLUT4 accumulates or is redistributed to a dense membrane compartment under basal conditions, and this abnormality is linked to impaired GLUT4 translocation to the plasma membrane in response to insulin.[221-223] These data are indicative of a trafficking or targeting abnormality impairing GLUT4 translocation in tissues derived from insulin-resistant subjects. Trafficking and translocation of GLUT4 is a complex process, and a long list of proteins involved in vesicle trafficking, membrane fusion, and the cytoskeleton could all be contributory. Additional study of pathways and factors involved in abnormal GLUT4 traffic may elucidate mechanisms causing human insulin resistance and establish targets for drug development.

Muscle contraction results in GLUT4 translocation and stimulates muscle glucose transport activity.[224] This effect occurs without any change in serum insulin concentration and does not involved activation of insulin receptors, PI-3 kinase, or Akt/PKB. In muscle from insulin-resistant humans and rodents, GLUT4 translocation is impaired in response to insulin but normal in response to acute exercise. This response appears to be at least partially dependent on increments in intracellular 5'AMP, and subsequent activation of 5'AMP-activated protein kinase (AMPK).[225] The maintenance of normal glucose uptake with muscle contraction highlights the therapeutic utility of regular exercise in diabetes.

Insulin Effector System Defects in Adipose Tissue. Fat accumulation in adipocytes is determined by the balance between triglyceride synthesis (glucose transport, FA uptake, and lipogenesis) and breakdown (lipolysis and FA oxidation). In regulating both functions, insulin alters the activity of relevant proteins through posttranslational modifications and alterations of gene expression. These proteins constitute the effector system for these biological effects of insulin in adipose tissue. In insulin-resistant individuals, adipose tissue is dysfunctional as an organ responsible for fuel storage and triglyceride turnover, and these defects adversely affect systemic metabolism.

a) **Lipogenesis.** Regarding lipogenesis, insulin augments availability of both glycerol and FAs for triglyceride synthesis by increasing the uptake of glucose in the adipose cell, as well as by activating lipogenic and glycolytic enzymes. One defect compromising lipogenesis is insulin's reduced ability to stimulate glucose transport into adipocytes needed for glycolytic flux to glycerol-3P required for synthesis of triglycerides. Stimulation of glucose transport in adipocytes is diminished due to defects in insulin signaling and GLUT4 translocation, as observed in skeletal muscle, but is further compromised by reductions in the expression and cellular content of GLUT4.[220-223] *De novo* synthesis of FAs for glycerol esterification and triglyceride synthesis may also be impaired. Some studies report that the adipocyte expression of genes involved in lipogenesis and FA esterification (e.g., diacylglycerol acyl transferase) is diminished in patients with obesity and insulin resistance. However, most of the FFAs used for triglyceride storage derive from circulating FFAs or from very low-density lipoprotein (VLDL) acted upon by lipoprotein lipase, and the contribution of *de novo* lipogenesis to adipocyte triglyceride content is small. For this reason, any abnormalities in *de novo* lipogenesis in adipocytes may not contribute heavily to abnormal lipid turnover.

b) **Antilipolysis.** In addition to abnormalities in lipogenesis, adipocytes display a general defect in their ability to store and retain triglycerides in patients with insulin resistance and T2D. Of key importance is the impaired ability of insulin to suppress lipolysis and the release of FFAs.[226] Lipolysis in normal subjects is exquisitely sensitive to inhibition by insulin, such that half-maximal suppression of lipolysis occurs at insulin concentrations well below those needed for significant stimulation of glucose uptake by skeletal muscle. Hormones regulate lipolysis in adipocytes via coordinated action involving two major effector systems, namely, hormone-sensitive lipase (HSL) and perilipins localized to the surface of lipid droplets. Lipolytic and antilipolytic (i.e., insulin) hormones exert opposite effects on HSL and perilipins by determining cyclic adenosine monophosphate (cAMP) availability and protein kinase A (PKA) activity. Catecholamines induce lipolysis and release FFAs from adipocytes by binding to β-adrenergic receptors coupled by heterotrimeric G proteins to adenylate cyclase, which increases production of cAMP and activates PKA. The two main targets for PKA phosphorylation are HSL and the perilipins.[227] The ability of insulin to antagonize hormone-induced lipolysis is to a large extent accounted for by its ability to lower cAMP levels, and thereby reduce PKA activity. The decrease in cAMP is mainly the result of an insulin-mediated phosphorylation and activation of phosphodiesterase 3B (PDE3B) via Akt/PKB.[228] Perilipins are localized at the surface of the lipid droplet in adipocytes and inhibit lipolysis by acting as a barrier against hydrolysis of the triacylglycerol by lipases. When PKA is activated, perilipin becomes phosphorylated and translocates away from the lipid droplet, which allows HSL to hydrolyze the adipocyte triglyceride core.[229] Insulin blocks lipolysis by inhibiting PKA-mediated phosphorylation of HSL and perilipin, thus reducing both HSL activity and its access to triglycerides in the fat droplet.

In insulin-resistant individuals, the dose-response curve for serum insulin versus reductions in FFAs is right-shifted such that FFAs are increased at any given insulin concentration over the broad range of physiological concentrations.[226] The impaired antilipolytic effects of insulin are due to defects in insulin signaling resulting in reduced activation of PDE3B, together with decreased levels of the lipid droplet proteins that protect stored triglycerides from lipolysis. The content of key perilipins and related proteins (e.g., CIDEA) in adipocytes has been shown to have an inverse correlation with lipolytic rates and a positive correlation with plasma glycerol in humans, and these proteins are reduced in patients with obesity and insulin resistance.[230-233] The mechanisms that downregulate adipocyte lipid storage proteins in obesity are not fully understood but may reflect decreased production and action of adiponectin as an autocrine/paracrine factor in adipose tissue[233-235] and attenuated activities of transcription factors that regulate expression of these proteins, such as CHREBPα/CHREBPβ and PPARγ. For example, insulin-sensitizing thiazolidinediones lower FFA levels, augment adiponectin secretion, and induce perilipin via a PPARγ-responsive element in its promoter region.[236]

Dysfunctional white adipose tissue is characterized by a decreased capacity to synthesize, esterify, and store triglycerides in a central lipid droplet, which results in higher levels of circulating FFAs. High FFAs contribute to toxic lipid accumulation of lipid in the liver and skeletal muscle and the exacerbation of insulin resistance in these organs. Cellular levels of lipid metabolites, such as DAG, ceramide, and long-chain fatty acyl-CoAs, are increased and act to impair insulin action and activate transcription factors such NF-κB that augment inflammatory processes. When the abnormalities in lipid turnover are considered together with the dysregulated secretion of adipocytokines in insulin-resistant states, adipose tissue can be viewed both as a central regulator of systemic glucose homeostasis and, when tissue function is impaired, as fundamental in the propagation of insulin resistance and CMD.[237]

Insulin Effector System Defects in Liver. Hepatic insulin resistance refers to impaired suppression of glucose production by insulin. The increase in HGO in T2D is due to a failure of insulin to inhibit both glycogenolysis and gluconeogenesis, and largely determines the severity of fasting hyperglycemia. Insulin regulates hepatic metabolism through acute posttranslational modifications of enzymes (e.g., phosphorylation) and through changes in gene expression. The metabolic enzymatic pathways responsible for glycogenesis/glycogenolysis and glycolysis/gluconeogenesis constitute effector systems for insulin in liver.

a) **Physiological Regulation of Hepatic Glucose Output.** Hepatic glucose production rates represent a balance between the inhibitory effects of insulin that predominate in the fed state and the stimulatory effects of counterregulatory hormones such glucagon, catecholamines, and glucocorticoids that prevail under fasting conditions. With insulin stimulation, the major portion of glucose uptake in liver is stored as glycogen. Insulin promotes glycogen synthesis by activating GS, which adds activated glucosyl groups to growing polysaccharide chains in the final step of glycogen synthesis.[238] Insulin's ability to stimulate GS in the liver requires proximal signaling through tyrosine phosphorylation of the docking protein IRS-2, activation of PI-3 kinase and Akt/PKB, followed by phosphorylation and inactivation of GS kinase-3 (GSK3). This results in reduced phosphorylation of GS, which augments its activity. In contrast, glucagon promotes glycogenolysis via formation of cAMP and activation of PKA, which in turn phosphorylates and activates phosphorylase kinase. Phosphorylase kinase converts inactive glycogen phosphorylase b into its active form phosphorylase a, which is responsible for the release of glucose 1-phosphate from glycogen polymers. Glycogenolysis is also regulated by the activity glycogen-associated protein phosphatases, and in liver the PP1 catalytic subunit is complexed with the G_L glycogen-binding subunit. Glycogen phosphorylase itself acts as a glucose sensor, because it can bind glucose, which renders it a better substrate for the $PP1/G_L$ phosphatase, thereby inactivating phosphorylase (i.e., converting it to its inactive b form) and diminishing glycogenolysis. Because the phosphorylated phosphorylase a acts as an allosteric inhibitor of the GS phosphatase activity of $PP1/G_L$, activation of GS is also enhanced. Thus, high glucose suppresses glycogenolysis and promotes glycogen synthesis in the liver and, conversely, low glucose favors glycogenolysis.

Gluconeogenesis is predominantly regulated through changes in gene expression for two key enzymes: (i) phosphoenolpyruvate carboxykinase (PEPCK), which catalyzes the rate-limiting step in glycogenolysis, and (ii) glucose-6-phosphatase (G-6-Pase), which catalyzes the final step producing free glucose for transport out of liver via GLUT2.[239] Transcription of the *PEPCK* gene is tightly regulated by cAMP. Glucagon increases cAMP, PKA activity, and phosphorylation of the transcription factor CREB, leading to induction of PEPCK, while this pathway is suppressed by insulin. Suppression of HGO by insulin also relies heavily on suppression of *PEPCK* and G-6-Pase gene expression through a complex process involving multiple transcription factors, including FOXO, SREBP-1c, LXR, Sp1, and others.[239-244] Under basal conditions, FOXO1 and FOXO3 proteins reside within the nucleus and actively regulate transcription of the G-6-Pase and *PEPCK* genes. Upon stimulation by insulin, Akt/PKB phosphorylates FOXO family members at conserved serine and threonine residues, which is followed by the dissociation of FOXO proteins from their DNA binding sites and exclusion from the nucleus. The relocation of FOXO results in reduced expression of G-6-Pase and PEPCK. On the other hand, glucagon increases expression of PGC1α via a cAMP-dependent process, and PGC1α participates as a coactivator with FOXO1 to increase the FOXO1-dependent transcriptional activity of G-6-Pase and PEPCK expression.[245] In this role, both FOXO1 and PGC1α cooperate to fully promote the induction of gluconeogenic genes in liver.

The suppressive effects of insulin on gluconeogenesis extend to additional transcription factors, as well as to systemic effects involving gluconeogenic substrates. For example, insulin stimulates SREBP1c, which contributes to the suppression of PEPCK and also promotes glycolysis and lipogenesis via regulation of glucokinase, pyruvate kinase, FA synthase, and acetyl CoA carboxylase.[246,247] In addition to direct hormonal effects on hepatocytes, HGO is diminished by insulin's ability to reduce delivery of gluconeogenic substrates to the liver, such as lactate, amino acids, and FFA. Insulin also minimizes counterregulatory effects of glucagon by inhibiting its secretion from the pancreatic α cell.

b) **Mechanisms of Hepatic Insulin Resistance.** Many of the defects underlying insulin resistance in the liver parallel those described in skeletal muscle and other tissues. These include decrements in insulin receptor tyrosine kinase activity, tyrosine phosphorylation of IRS-2, which serves as the principal IRS docking protein in liver, PI-3 kinase phosphorylation, and activation of AKT. Defects in insulin signal transduction have been attributed to serine phosphorylation of the insulin receptor and IRS-2 as a result of increased intracellular FAs and metabolites that activate PKC and JNK. The signaling defects impair insulin's ability to stimulate glycogenesis and inhibit gluconeogenesis, resulting in unrestrained HGO. The reduced ability of insulin to stimulate GS and promote glycogenesis is due to an inability to phosphorylate and inactivate GSK3. Inhibition of glycogenolysis is similarly impaired via a reduced ability to activate phosphodiesterase, which limits conversion of cAMP to AMP. The resulting higher levels of cAMP activate PKA, causing ongoing phosphorylation and activation of phosphorylase kinase. This allows glycogen phosphorylase a to promote the ongoing release of glucose-1P from glycogen, conversion to glucose-6P, and export of glucose from the liver following the action of glucose-6 phosphatase. In addition, glycogen phosphorylase a retains PP1 in its bound and inactive state, which prevents it from dephosphorylating and activating GS.

KEY POINTS

- Insulin resistance in target tissues involves defects in insulin signal transduction including downregulation of insulin receptor (IR) number, decreased receptor tyrosine kinase activity, and reduced tyrosine phosphorylation of IR substrate (IRS) docking proteins. This is due in part to serine phosphorylation of IR and IRS molecules by inflammation and stress-activated serine kinases. Additional mechanisms of insulin resistance involve defects in tissue-specific biological effector systems.

The defects in insulin signaling also affect the complex transcriptional network that regulates glycolysis and gluconeogenesis. Insulin is less able to inhibit gluconeogenesis in T2D because insulin-induced phosphorylation and nuclear exclusion of FOXO-1, stimulation of SREBP1, and effects on other nuclear factors promoting gluconeogenesis are impaired. At the same time, the effects of counterregulatory hormones to increase hepatic glucose production are unabated. Glucagon levels are increased in T2D and stimulate adenyl-cyclase activity in hepatocytes, leading to increased intracellular cAMP levels. This activates PKA and subsequent phosphorylation and activation of the nuclear transcription factor CREB. CREB is a master positive regulator of gluconeogenic gene expression in conjunction with other nuclear coactivators, including CBP (CREB-binding protein), TORC2 (transducer of regulated CREB activity 2), and other transcription factors, including PGC1α, FOX01, and HNF-4α that positively activate the gluconeogenic program.[248] Once the liver is insulin-resistant, phosphorylation of these cofactors is impaired, resulting in continued high levels of FOX01, TORC2, CBP, and SREBP1 in the nucleus that sustain ongoing gluconeogenesis.

CELL STRESS RESPONSES, NUTRIENT SENSING, AND INSULIN RESISTANCE

The described defects involving the insulin receptor, signal transduction, and hormone effector systems are not self-created, but rather arise as a consequence of cell stress responses that are integral to the insulin resistant state, as well as nutrient stress responses involving nutrient sensor pathways. Fuel metabolism, in particular, can interact with hormone signaling pathways to regulate a broad range of cell functions and link nutrient availability with insulin's ability to regulate metabolism. Chronic nutrient excess can activate cell stress responses and impair signal transduction via transcriptional and posttranscriptional mechanisms. Three stress responses (oxidative stress, inflammation, and ER stress) and three predominant pathways for nutrient sensing will be discussed (mammalian target of rapamycin [mTOR], AMP kinase, and hexosamine biosynthetic pathway).

Cell Stress Responses and Insulin Action

Oxidative Stress. In addition to mediating β cell dysfunction in T2D[126] (see Mechanisms Causing Pancreatic β Cell Dysfunction section), oxidative stress represents an important factor in the development of insulin resistance.[249] The mediator of oxidative stress is an increase in the formation of ROS within cells due to increased generation and/or compromised antioxidant systems. The predominant portion of ROS is produced in cells during mitochondrial respiration and is augmented by nutrient excess, physical inactivity, and hyperglycemia. High levels of ROS activate NF-κB and upregulate expression of proinflammatory genes such as TNFα, IL-6, and C-reactive protein.[250] Oxidative stress activates serine kinases that impair insulin signal transduction by phosphorylating insulin receptor and IRS molecules, and also promotes proteosomal degradation of IRS-1.

Inflammation. Low-grade systemic inflammation in patients with insulin resistance is marked by elevated levels of circulating proinflammatory cytokines and other biomarkers of inflammation. Various factors including elevated saturated FAs, oxidative stress, ER stress, and cytokines can all initiate proinflammatory responses by activating the JNK/AP-1 and IKKb/NF-κB signaling pathways.[197] JNK-1 and IKKb serine kinases activate the transcription factors AP-1 (C-Jun/Fos) and NF-κB, which then activate serine kinases that phosphorylate the insulin receptor and IRS proteins[180-183] and increase transcription of *SOCS* genes.

Endoplasmic Reticulum Stress. ER stress can be an adaptive cellular response to an accumulation of unfolded or misfolded proteins in its lumen, but can also be triggered by other factors, including chronic nutrient excess, high FA concentrations, and oxidative stress.[251] ER stress activates the JNK pathway, with subsequent serine phosphorylation of IRS-1 and the development of insulin resistance. The mechanism for JNK activation involves transmembrane ER proteins with luminal domains responsive to ER stress signals and cytoplasmic effector domains that influence intracellular pathways. One of these stress transducers is inositol-requiring enzyme 1, a serine-threonine kinase that links ER stress to JNK activation. Obesity and extended periods of high-fat feeding can induce the ER stress response in adipose tissue and liver, as indicated by ER stress markers such as PERK, eIF2α phosphorylation, and JNK activation.

Nutrient Sensors and Nutrient Stress

The Mammalian Target of Rapamycin Signaling Pathway. mTOR is a central signal integrator that receives signals arising from growth factors, nutrients, and cellular energy metabolism, and then activates pathways that control cell growth as well as insulin action.[252] The C-terminal region of mTOR is a serine-threonine protein kinase and exists in two functionally distinct complexes dubbed mTOR complex 1 (mTORC1) and mTORC2. mTORC1 can impair insulin signaling via its ability to activate S6K, which then can phosphorylate serine residues of IRS-1, resulting in desensitization of the PI-3 kinase/Akt pathway.[249,250] High levels of glucose and amino acids, especially leucine, lead to an increase in mTOR activity, while depletion of these metabolic substrates or mitochondrial (e.g., oligomycin) and glycolytic (e.g., 2-deoxyglucose) inhibitors attenuate mTOR activity. Thus, activation of S6K by mTOR serves as a mechanism by which nutrient excess can desensitize insulin action through serine phosphorylation of IRS-1.[255] Rapamycin in a complex with its intracellular receptor FKBP12 can bind and inhibit in mTOR, which results in enhanced insulin-mediated glucose uptake by inhibiting phosphorylation of S6K. The proximal signaling component immediately responsible for inhibiting the mTOR pathway is the tuberous sclerosis complex (TSC). TSC can integrate information from the insulin signaling cascade and the AMPK signaling pathway. These multiple steps involved in nutrient sensing by the TSC and mTOR represent attractive targets for treating insulin resistance in metabolic diseases caused by nutrient excess, such as T2D and obesity.

AMPK Signaling Pathway. The AMPK signaling pathway is activated by elevation of the AMP/ATP ratio. The pathway is switched on by nutrient deprivation leading to accumulation of AMP, or perturbations that interfere with ATP synthesis, such as glucose deprivation, hypoxia, metabolic inhibitors (2-deoxyglucose), and disruption of oxidative phosphorylation. Once activated, it switches on fuel metabolism pathways that generate ATP, while inhibiting anabolic processes that consume ATP.[256] To conserve ATP, AMPK activation suppresses protein synthesis by inhibiting the mTOR pathway and by inhibiting translational elongation of proteins via activation of elongation factor-2 kinase. To generate ATP, AMPK activates processes such as glucose uptake, glycolysis, FA oxidation, and mitochondrial biogenesis, while switching off anabolic processes that consume ATP, including FA and cholesterol biosynthesis, gluconeogenesis, and glycogenesis. To enhance the capacity for ATP generation, AMPK appears to promote mitochondrial biogenesis through concerted action with another metabolic sensor, the NAD^+-dependent deacetylase SIRT1, and the PGC-1α transcriptional co-factor. In skeletal muscle, AMPK stimulates lipid oxidation, increases insulin sensitivity, and mediates contraction-induced increments in glucose uptake during exercise.[225,257] In liver, AMPK activation suppresses gluconeogenic enzyme expression and leads to decreased blood glucose values, while FA oxidation is stimulated, and cholesterol and triglyceride biosynthesis are blocked.[259] These biological actions are the result of phosphorylation and inactivation of both acetyl-CoA carboxylase (ACC) and 3-hydroxy-3-methylglutaryl coenzyme A reductase (HMG-CoA reductase) by AMPK. The phosphorylation of ACC is central to AMPK's ability to promote FA oxidation, as this reduces its activity and results in decreased production of malonyl-CoA, an inhibitor of carnitine palmitoyltransferase I (CPT1). The reduction in malonyl-CoA relieves the inhibition of CPT1 and promotes CPT1-mediated transport of FAs into the mitochondria for oxidation. At the transcriptional level, AMPK blocks lipogenesis by limiting endogenous LXR ligand production, which inhibits LXR-dependent transcription of SREBP-1.[259]

AICAR has been used experimentally to study the effects of AMPK activation on metabolism and insulin signaling pathways.[260] AICAR is an adenosine analog that mimics AMP and activates AMPK signaling through direct binding. AICAR has been shown to stimulate glucose uptake, increase adiponectin secretion, and inhibit production of cytokines such as TNFα and IL-6. AMPK is activated by the insulin-sensitizing hormone adiponectin, and two classes of antidiabetic drugs, biguanides and thiazolidinediones, both act in part by activation of AMPK.

Branched-Chain Amino Acids. Metabolomic studies have shown that serine and glycine levels are positively correlated with hyperinsulinemic clamp measures of insulin sensitivity, while branched-chain amino acids (BCAAs), aromatic amino acids, and C3 and C5 acylcarnitines are associated with insulin resistance.[261,262] Elevated BCAA levels confer a higher risk of developing T2D, underscoring the association with insulin resistance.[263] Increased BCAA concentrations could result from dietary sources or due to greater protein breakdown and release into the circulation as a result of insulin's decreased ability to inhibit proteolysis. The mechanistic link with insulin resistance has not been fully elucidated but may involve activation of the mTOR complex and S6 kinase pathway.[264]

The Gut Microbiome. Metagenomic studies have revealed that approximately 90% of the bacterial species present in the gut of adults belongs to two phyla, *Bacteroides* (gram-negative) and *Firmicutes* (gram-positive). In patients with obesity and metabolic diseases, investigators have reported alterations in gut microbiota that include a reduction in bacterial diversity together with a relative enrichment in *Firmicutes* and reduction in *Bacteroides* species. The question as to whether changes in these bacterial populations can influence health has been an active area of research, and several mechanisms have been proposed.[265,266] First, the bacteria secrete metabolites that can act locally in the gut to influence immune cells in the intestinal wall or bind gut epithelial receptors. An example of the latter would include bacterial-derived medium-chain FAs that can activate G protein–coupled receptors (GRP40 and GRP120) on the surface of enteroendocrine L-cells in the intestine and influence secretion of the incretin GLP-1. The second possibility is these bacterial products increase intestinal permeability, allowing metabolites to be absorbed into the bloodstream, where they can alter metabolism in distal tissues. Bacterial products that can reach the systemic circulation include bacterial lipopolysaccharides, bacterial DNA, short-chain FAs, and bile acid derivatives, which potentially can influence insulin sensitivity, inflammation, and energy metabolism.[267]

Most of this work has been performed in rodents, in particular gnotobiotic and germ-free mice receiving fecal transplants from mice with metabolic disease. For example, recolonization of the intestine of germ-free mice with gut microbiota obtained from obese mice induces obesity in the host.[268] Far fewer data are available in humans, and the majority of studies are descriptive, assessing differences in microbiota in cases versus controls or changes over time following an intervention. One randomized study conducted fecal transplants from lean or obese donors to obese human hosts showed that transplants from lean donors were associated with improved insulin sensitivity without any effect on body weight over a 6-week period.[269] However, within 1 year, the original microbiota had reestablished itself, and insulin resistance returned to pretransplant levels. Of note, the metabolic responses to different diets have been shown to vary between individuals depending on the composition of their gut microbiota. For example, a randomized clinical study reported that participants with high Prevotella-to-Bacteriodes (P/B) ratio were more susceptible to lose body fat on diets high in fiber than subjects with a low P/B ratio.[270]

The impact of the gut microbiota on T2D has not been elucidated, and the therapeutic potential of manipulating gut bacterial populations will require additional study in humans. Bacterial populations are altered in the short term by diet and other factors, and this plasticity makes it more difficulty to ascribe a specific bacterial mix as a causal factor in chronic disease. Fecal transplantation is being used for treatment of some human diseases (*Clostridium difficile* colitis, inflammatory bowel disease), so there is hope that eventually gut microbiota can be targeted for therapeutic benefits in metabolic diseases.

The Hexosamine Biosynthetic Pathway, TRIB3, and Glucose-Induced Insulin Resistance

Hyperglycemia-induced insulin resistance in T2D is due to the ability of glucose to directly impair the activity of the glucose transport system in target cells. Marshall and others have demonstrated that one important mechanism underlying glucose-induced insulin resistance involves glucose metabolism through a minor intracellular pathway, the hexosamine biosynthetic pathway.[271] Glutamine:fructose-6-phosphate amidotransferase is the rate-limiting enzyme of this pathway that leads to the production of glucosamine-6-phosphate. Glucosamine-6-phosphate is then metabolized to UDP-*N*-acetylglucosamine (UDP-GlcNAc), which serves as the substrate for attachment of *O*-GlcNAc to proteins catalyzed by O-linked N-acetylglucosamine transferase. Thus, increased glucose flux through the hexosamine biosynthetic pathway leads to increased posttranslational O-linked glycosylation of cytoplasmic and nuclear proteins,[272] which can modulate their enzyme activities, proteasomal degradation, and binding with DNA and other proteins. UDP-GlcNAc levels can fluctuate with the availability of nonesterified FAs, uridine, glutamine, as well as glucose, and in this way the hexosamine biosynthetic pathway acts as a nutrient sensor and regulator.

Increased glucose flux through the hexosamine biosynthetic pathway results in reduced rates of basal and insulin-stimulated glucose transport in adipocytes and muscle cells.[212,213,273] However, the mechanisms by which products of the hexosamine biosynthetic pathway induce insulin resistance have not been fully elucidated. Increased metabolic flux through this pathway results in increased O-glycosylation of the insulin receptor, IRS1, Akt/PKB, GLUT4, GSK3β, and the transcription factor Sp1, and this can impair the functional capabilities of these proteins or accelerate their proteasomal degradation. For example, increased O-glycosylation of the insulin receptor is accompanied by a decrease in insulin-stimulated receptor autophosphorylation.[272] O-glycosylation can impair phosphorylation and DNA binding of C/EBPβ and decrease NK-κB binding, with IκB freeing NF-κB for relocation to the nucleus and induction of proinflammatory gene transcription. However, a key mechanism for glucose-induced insulin resistance appears to involve Tribbles homolog 3 (TRIB3). TRIB3 is a glucose-induced gene that encodes a pseudokinase capable of binding and blocking protein tyrosine phosphorylation sites. Specifically, TRIB3 can block activation of AKT by occupying its phosphorylation site and inhibit insulin signal transduction.[274] TRIB3 is significantly upregulated in skeletal muscle of T2D patients and hyperglycemic rodent models in a manner that is correlated with circulating glucose.[274] The ability of glucose to induce *TRIB3* gene expression is dependent on its metabolism via the hexosamine biosynthetic pathway and O-glycosylation of Sp1. Moreover, glucose-induced insulin resistance in diabetic streptozotocin-treated mice was found to be dependent upon upregulation of TRIB3 in experiments involving muscle-specific *TRIB3* deletion.[213]

KEY POINTS

- Insulin action defects in type 2 diabetes are induced by cell stress responses that are integral to the insulin resistant state, as well as nutrient stress responses involving nutrient sensor pathways. Cell stress is generated an excess of glucose and lipids inducing oxidative stress, inflammation, and endoplasmic reticulum stress. These responses are driven by nutrient sensor pathways involving mammalian target of rapamycin signaling, adenosine monophosphate kinase, and the hexosamine biosynthetic pathway.

SYNDROMES OF SEVERE INSULIN RESISTANCE

Heterogeneity of Type 2 Diabetes

T2D is a heterogeneous disease across spectrums of age, BMI, and the degree to which defects in insulin secretion versus insulin action contribute to hyperglycemia. In addition, there are distinctive phenotypes that occur relatively uncommonly associated with identifiable genetic defects, unique syndromic features, or other disease processes. These are listed in Table 33.1. Many of these are described in other chapters or referenced publications as indicated in the table, and severe insulin resistance types A and B will be addressed in this chapter. In aggregate, metabolic and phenotypic heterogeneity in T2D is indicative of disease complexity involving varying molecular defects, genetic abnormalities, behaviors, and gene–environment interactions.

Severe Insulin Resistance

Severe Insulin Resistance Type A. These patients carry different mutations in the insulin receptor gene.[275,276] The syndrome may be characterized by autosomal dominant or recessive inheritance and involve mutations that can be heterozygous or homozygous when mutations cause relatively mild defects in receptor function. These mutations impair either insulin binding or signal transduction through receptor tyrosine kinase activity.[277,278] Other patients who conform with this clinical phenotype do not have mutations in the insulin receptor gene and may have as yet unidentified mutations in genes encoding downstream signaling molecules (e.g., *AKT2*, *AS160*). Clinically, these patients have extreme hyperinsulinemia and most often present as adolescent or young females with acanthosis nigricans, abnormal glucose tolerance, hyperandrogenism, and oligomenorrhea. In males, the disease has less distinctive features, and patients may only present with acanthosis nigricans. In some patients, prominent musculature has been described that may result from hyperandrogenism in females or crossover stimulation of the insulin-like growth factor-1 receptor as a consequence of elevated serum insulin concentrations.

Severe Insulin Resistance Type B. Type B severe insulin resistance is the result of circulating antibodies directed against the insulin receptor that block insulin binding and receptor activation.[279] The clinical presentation features hyperinsulinemia, hyperglycemia, acanthosis nigricans, and evidence of autoimmunity, if not the presence of overt autoimmune disorders such as rheumatoid arthritis, Raynaud's phenomenon, or systemic lupus erythematosus. Consistent with other autoimmune disorders, the disease most often occurs in middle-aged females, but can also occur in adolescents and the elderly, and has a higher incidence in Blacks. Laboratory findings include serum insulin receptor blocking antibodies, proteinuria, and elevated antinuclear antibody, erythrocyte sedimentation rate, and serum immunoglobulin G levels. On examination, patients can be found to have arthritis, vitiligo, alopecia, and enlarged salivary glands.

Patients can require high doses of insulin to control hyperglycemia, sometimes greater than 1,000 units/day, when use of concentrated insulin preparations (e.g., U500) is warranted. Other patients may have more mild degrees of abnormal glucose tolerance but still display extreme endogenous hyperinsulinemia. The clinical course can vary with changing titers of antireceptor antibodies or even undergo spontaneous remission for periods of months to years. Treatment involves therapy for the underlying autoimmune process, glucocorticoids, and/or plasmapheresis in severe cases.

Paradoxically, some patients may present with or develop hypoglycemia.[280] While directed against the insulin-binding α subunit, the receptor antibodies can have assorted biological effects. In addition to blocking insulin binding, some antibodies can have agonist properties and stimulate glucose transport and metabolism, which can explain hypoglycemia in some patients over the course of their disease.[281] Antibodies isolated from hyperglycemic or hypoglycemic patients may acutely stimulate insulin receptor activity *in vitro*; however, cells likely become refractory to these effects, which can explain the changing clinical course and heterogeneity of clinical presentations. In hypoglycemic patients, elevated insulin levels may lead to a false diagnosis of insulinoma, and it is important to test for the presence of insulin receptor antibodies in these patients.[282]

NATURAL HISTORY OF TYPE 2 DIABETES AS AN END-STAGE MANIFESTATION OF CARDIOMETABOLIC DISEASE

The Spectrum of Cardiometabolic Disease

In addition to examining the evolution of T2D as a disease of glucoregulation, it is appropriate to include its pathophysiology in the larger context of CMD. In this light, T2D is an end-stage manifestation of a single disease process affecting both metabolism and the vasculature, which explains why T2D, CVD, NAFLD, and obesity are epidemiologically linked and often present as comorbidities in single patients. The spectrum of CMD is shown in Fig. 33.17. The core abnormality in the progression of CMD is insulin resistance.[165] The classic cardinal manifestations of insulin resistance include normoglycemia or hyperglycemia in the face of hyperinsulinemia due to defects in insulin-stimulated glucose uptake in muscle and suppression of hepatic glucose production. However, the glucoregulatory defect is associated with additional pathophysiological processes that adversely impact both metabolism and the vasculature, including: (i) impaired mitochondrial function and substrate oxidation; (ii) increased inflammation and oxidative stress; (iii) dysfunctional and inflamed adipose tissue with altered secretion of adipocytokines; (iv) impaired lipid storage in adipocytes associated with accumulation of "ectopic" lipid within muscle and liver cells; (v) alterations in lipids and lipoproteins contributing to CVD risk, including increased large triglyceride-rich VLDL, lower HDL, and increased concentrations of small dense low-density lipoprotein molecules; (vi) abnormalities in vasoregulation due to a reduction in endothelial nitric oxide synthase activity and nitric oxide production; (vii) a clotting diathesis featuring elevated PAI-1 and fibrinogen levels; and (viii) functional and structural abnormalities affecting the myocardium predisposing to heart failure with preserved ejection fraction, congestive heart failure, and atrial fibrillation. It is not clear whether the glucoregulatory defect precedes the development of these latter processes or *vice versa*. For this reason, in the context of what initiates and promulgates CMD, the combination of these multiple pathophysiological processes, together with defects in glucoregulation, are referred to as the insulin-resistant state.

The insulin-resistant state can remain subclinical for decades; however, the progression of CMD gives rise to clinically identifiable states of high risk in the form of metabolic syndrome, prediabetes, prehypertension, dyslipidemia, ventral adiposity, and hepatic steatosis.[165] While there is no practical method of directly measuring insulin resistance in the clinic, its presence can be denoted in patients by the presence of these traits.[5,283] These clinical manifestations indicate that the pathophysiological processes integral to the insulin-resistant state are operational, placing patients at risk of end-stage metabolic and vascular disease outcomes, including T2D, nonalcoholic steatohepatitis (NASH), hypertension, myocardial infarction, stroke, myocardial dysfunction, and chronic kidney disease.

Role of Obesity

Obesity is a chronic disease of energy balance driven by dysregulated interactions involving satiety factors and the CNS resulting in increased caloric intake and an excess in adipose tissue mass (see Obesity and Nutrition). The increase in adiposity causes chronic complications that confer increased morbidity and mortality.[136] The relationship between body weight gain and CMD is complex. The correlation between generalized adiposity and insulin sensitivity indicates that only approximately 11% of individual variability in insulin sensitivity can be explained by BMI.[25] Many individuals with CMD who progress to T2D and/or CVD are lean. In addition, a certain proportion of patients with BMIs in the overweight or obesity range are insulin-sensitive, do not develop metabolic syndrome traits, and are not at increased risk of T2D and CVD.[5,284] These patients are referred to as the metabolically healthy obese, and represented approximately 15% to 20% of US adults with overweight or obesity in the National Health and Nutrition Examination Survey cohort.[285] Thus, obesity is not necessary nor sufficient as a cause of CMD and T2D.

However, if weight gain occurs on an insulin-resistant background, there is preferential accumulation of fat in the intraabdominal

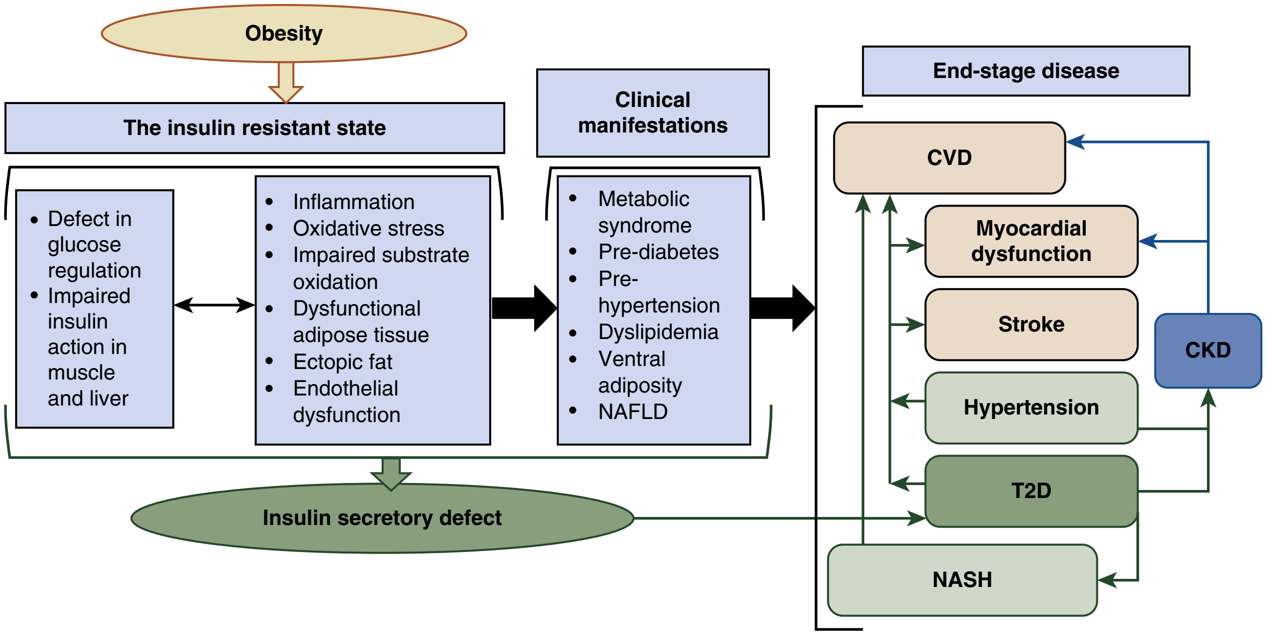

Fig. 33.17 **The spectrum of cardiometabolic disease.** Pathophysiological properties of the insulin-resistant state *(gray)* produce clinical manifestations that mark patients as insulin-resistant and indicate the presence of cardiometabolic disease. End-stage manifestations of these disease process include the vascular diseases in red (cardiovascular disease [CVD], myocardial dysfunction, stroke) and metabolic diseases in green (type 2 diabetes [T2D], nonalcoholic steatohepatitis [NASH], hypertension). The presence of the metabolic diseases further exacerbates vascular pathogenesis and contributes to chronic kidney disease (CKD). Obesity can exacerbate insulin resistance and drive the progression of cardiometabolic disease.

compartment, which contains an increased number of resident macrophages[92,286] predominantly involving classically activated M1 and a lesser proportion of alternatively activated M2 macrophages. These resident macrophages secrete cytokines and other factors that crosstalk with adipocytes and alter the systemic release of adipocytokines from adipose tissue.[237] Altered release of adipose tissue factors such as adiponectin, resistin, free FAs, leptin, angiotensinogen, and PAI-1, and increased production of inflammatory cytokines including IL-6, IL-1, and TNFα alter metabolism in multiple organs. Adipocytes residing in the inflamed adipose tissue environment are dysfunctional, exhibiting insulin resistance with respect to simulation of glucose transport and antilipogenesis, and reach a limit where they are unable to store further calories as fat. Serum levels of FFAs become elevated, and ectopic lipid accumulates within liver and muscle cells, leading to NAFLD and worsening insulin resistance. With the development of obesity, there is a greater need to dispose of increased calories, which further augments lipid deposited within muscle and liver cells and intensifies processes such as inflammation, oxidative stress, and glucose intolerance. The systemic inflammation and oxidative stress activate NF-κB, further propagating inflammatory pathways and production of cytokines. Intracellular levels of DAGs and ceramides also increase and activate both serine/threonine kinases, which desensitize insulin action via phosphorylation of signaling molecules (i.e., insulin receptor substrate-1 and insulin receptor).[283] Adiponectin is an insulin-sensitizing hormone produced only by adipocytes, and reduced plasma levels are associated with insulin resistance, obesity, and CVD.[288,289] Diminished production of adiponectin is a mechanism that can explain metabolic disease both by adding to defects in adipocyte function as an autocrine/paracrine factor,[95,234] and in the vascular wall by promoting foam cell formation and fatty streak development via reduced inhibition of cholesterol accumulation in macrophages.[95,290] These molecular events exacerbate insulin action defects in muscle and liver, worsen systemic inflammation and metabolism, and impel progression towards end-stage developments in CMD.

Thus, there is an interaction between excess adiposity and insulin resistance to worsen pathophysiological processes associated with the insulin-resistant state, and this explains why obesity is a major risk factor for the development of metabolic syndrome and prediabetes, as well as for progression to overt T2D, NASH, and CVD. Clinically, the critical point is that, in those patients with elevated BMI and insulin resistance, weight loss becomes a highly effective therapeutic modality to prevent and treat CMD.[165]

Implications for Type 2 Diabetes Prevention and Treatment

Within the context of CMD, T2D can be seen as an end-stage development of a larger chronic disease process. Patients who remain normoglycemic continue to exist in a state of accelerated atherosclerosis and are at increased risk of CVD events. Patients who are predisposed to pancreatic β cell exhaustion develop prediabetes, followed by progression to overt T2D. The perspective of T2D as an end-stage development of a chronic progressive disease has two salient clinical implications. First, this

KEY POINTS

- In most patients, type 2 diabetes (T2D) is an end-stage manifestation of cardiometabolic disease (CMD), with insulin resistance as the core mechanism responsible for disease progression to prediabetes and the metabolic syndrome to overt T2M. Other end-stage manifestations include cardiovascular disease, functional and structural myocardial disease, stroke, hypertension, nonalcoholic fatty liver disease and steatohepatitis, and chronic kidney disease. Obesity can exacerbate insulin resistance and impel CMD progression. This perspective emphasizes opportunities for primary, secondary, and tertiary disease prevention, with weight loss being an effective intervention, and points to the need for comprehensive vascular and metabolic care in patients with T2D.

assimilates the framework for designing rational strategies for primary, secondary, and tertiary prevention. It is no longer sufficient to wait until diabetes becomes overt to begin treatment. Given the increasing burden of patient suffering and social costs exacted by T2D, it becomes imperative to intervene early to halt CMD progression. Primary prevention is appropriate for individuals at risk of the insulin-resistant state. While the insulin-resistant state is largely subclinical, individuals at risk can be identified based on risk stratification paradigms,[5,15], family history, *in utero* exposure to gestational diabetes, genetic factors, ethnicity, behavioral factors, and social and environmental determinants of health. Primary preventive strategies are warranted, such as public health messaging, the built environment, access to unprocessed foods, healthy gestation, economic viability, stress reduction, weight control, and access to preventive care. Once patients develop the clinical manifestations of the insulin resistant state (e.g., metabolic syndrome, prediabetes, nonalcoholic fatty liver, prehypertension), more aggressive and targeted secondary preventive interventions are needed, such as 7% to 10% weight loss,[136,291] physical activity and healthy meal plan prescriptions, and control of dyslipidemia, abnormal glucose tolerance, and elevated blood pressure.

The second implication applies to patients who have progressed to overt T2D. In addition to T2D, other end-stage manifestations of CMD include coronary artery disease, stroke, functional myocardial impairment, hypertension, and NASH. Once CMD progresses to end-stage disease outcomes, aggressive tertiary management and comprehensive care is required, because these diseases adversely impact each other. Development of T2D worsens NASH and further accelerates atherogenesis and myocardial dysfunction, predisposing to myocardial infarction and chronic heart failure. T2D and hypertension lead to a decline in renal function, which exacerbates both CVD and metabolic pathophysiology. From this perspective, treatment of diabetes encompasses much more than glycemic control and must concomitantly encompass the prevention and treatment of all end-stage manifestations of CMD.

The neglect for early intervention has failed our patients and our societies, given the rising rates of diabetes and the suffering and social costs this entails internationally. In particular, because the clear majority of patients with CMD have overweight and obesity, weight loss therapy using the evidence-based tools of obesity medicine are too often neglected, despite documentation that they are highly effective in preventing and treating T2D.[136]

DIABETES AND PREGNANCY AND THE MOTHER

Metabolic Effects of Pregnancy

Pregnancy is characterized by hormonal changes that influence maternal glucose, protein, and fat metabolism. In preparation for the demands of later pregnancy, early pregnancy is an anabolic phase in which there is an accumulation of maternal fat stores. Glucose is the major and obligate source of fuel for the fetoplacental unit and is mainly transported by glucose transporter-1. In early pregnancy there is a small decrease in insulin sensitivity, accompanied by modest rises in insulin secretion, followed by an increase in insulin sensitivity from approximately gestational weeks 7 to 18.

Late pregnancy is a catabolic state that ensures that energy stores are directed to the fetus, even at the expense of the mother, and has been described by Freinkel as a state of accelerated starvation.[1] This is characterized by marked increases in maternal insulin resistance, with insulin sensitivity dropping by 60%.

KEY POINTS

- Pregnancy is associated with a small decrease in insulin sensitivity up to week 7, then an increase in insulin sensitivity up to week 18, and then a 2- to 3-fold increase in insulin resistance up to term. This has major implications for diabetes in pregnancy management.

The increase in insulin resistance diverts glucose to the fetus. The increased insulin resistance is accompanied by a 3-fold increase in insulin secretion. This may not be entirely as a result of a compensatory response of individual β cells, as both increased β cell hypertrophy and hyperplasia have been observed in animal studies. Despite there also being an increase in basal hepatic gluconeogenesis, maternal fasting glucose levels fall during normal pregnancy.

The increase in insulin resistance of pregnancy is largely mediated by placental hormones and cytokines, in particular human placental lactogen (HPL), placental growth hormone (GH), tumor necrosis factor-α (TNF-α), corticotropin-releasing hormone (CRH), and progesterone. There is a marked rise in HPL, placental GH, TNF-α, and CRH toward the end of the second trimester. There is also an increase in maternal insulin-like growth factor-I, cortisol, prolactin, and free fatty acids (FFAs), with the former two driven by placental GH and CRH, respectively.

Lipid metabolism is altered later in pregnancy, with a marked rise in triglyceride levels and, to a lesser extent, cholesterol. Increased lipolysis mobilizes fatty acids, which serve as an alternative fuel source for the mother. Placental lipoprotein lipase (LPL) also hydrolyses dietary triglycerides to FFAs, which become available for fetal uptake.[2] The increase in FFAs predisposes to higher plasma levels of ketone bodies during periods of fasting. The metabolic adaptations

in pregnancy are geared toward protein accretion by the maternal-fetal unit. Maternal protein turnover appears to be increased, with protein synthesis increasing by 25%, against a 10% decrease in amino acid oxidation. Circulating levels of amino acids are lower during pregnancy, but it is unclear if this is related to increased fetal uptake of amino acids, accelerated maternal uptake of amino acids, or splanchnic pooling.

The net result of the changes in maternal macronutrient metabolism is to prioritize the supply of glucose to the fetus, provide an adequate alternative energy source for the mother in the form of ketones and FFAs, and protect the mother against uncontrolled protein catabolism.

Classification of Diabetes in Pregnancy

Diabetes in pregnancy, also known as hyperglycemia in pregnancy (HIP), is generally divided into diabetes that predated the pregnancy (type 1 diabetes mellitus [T1DM], type 2 diabetes mellitus [T2DM], secondary forms of diabetes, and monogenic diabetes) and hyperglycemia that is first detected in pregnancy (Fig. 34.1). Hyperglycemia which is first detected in pregnancy includes those with likely pre-existing diabetes that was undiagnosed. Hence, hyperglycemia which is first detected in pregnancy into "overt diabetes in pregnancy" (ODIP) and "gestational diabetes mellitus" (GDM). In this classification, ODIP refers to women who had an oral glucose tolerance test (OGTT) result meeting the non-pregnant criteria for diabetes, and GDM refers to the milder form of HIP.[3] This classification assumes that women with ODIP are at higher risk of adverse pregnancy outcomes and are more likely to have diabetes post-partum, but this is not always the case.

In reality, it is increasingly recognized that diabetes in pregnancy represents a spectrum, from preexisting T1DM and T2DM to GDM, which classically was thought to develop toward the end of the second trimester. There is growing appreciation that many women have prediabetes or mild hyperglycemia before pregnancy, leading to GDM early in pregnancy. Criteria for early GDM are under active debate.

Pathogenesis of Gestational Diabetes Mellitus and Diagnosis

GDM has been defined as carbohydrate intolerance that is first discovered during pregnancy. However, it is now recognized that it is a heterogeneous disorder: some women diagnosed with GDM have preexisting unrecognized glucose intolerance, and many have subtle metabolic disturbances. The diagnosis of GDM is controversial, with varying criteria used in different parts of the world, and limited data are available regarding what level of glucose is harmful in early pregnancy.

GDM is classically considered to develop toward the end of the second trimester of pregnancy, coinciding with the rise in insulin resistance of late pregnancy. The increase in insulin resistance is similar between women with GDM and those with normal glucose tolerance.[4,5] The major difference resulting in hyperglycemia is that women with GDM fail to adequately compensate with increased insulin secretion, with a most notable decrease in first-phase insulin response.[4]

It is now recognized that more subtle degrees of hyperglycemia may develop early in pregnancy, although the significance remains unclear. It has also been proposed that an exaggerated fetal glucose phenomenon occurs when fetal hyperinsulinemia is established early in pregnancy.[6] This increases glucose flux across the placenta and continues to expose the fetus to glucose excess, without the mother necessarily becoming hyperglycemic. This highlights the active role that the placenta plays in determining fetal growth during HIP, although the mechanisms are not fully understood.

In GDM the maternal metabolic derangement is not limited to that of glucose metabolism. In the fasting state, FFAs and triglycerides are higher than in normal pregnancy.[2] Insulin-sensitive amino acids such as leucine, isoleucine, and valine are increased. Transplacental transfer of these additional nutrients to the hyperglycemic fetal milieu further fuels excessive fat accretion and growth. There is some evidence that maternal FFA and triglycerides may be a stronger predictor of fetal fat accretion and large for gestational age (LGA) babies in GDM than glucose.[2]

TABLE 34.1 Diagnostic Criteria for Gestational Diabetes

Criterion	Glucose Load	Abnormal Values Required	Fasting mmol/L (mg/dL)	1-Hour mmol/L (mg/dL)	2-Hour mmol/L (mg/dL)	3-Hour mmol/L (mg/dL)	Comment
O'Sullivan and Mahan, 1964	100g	2	5 (90)	9.2 (166)	8.1 (146)	6.9 (124)	Based on whole blood, no longer used
NDDG, 1979	100 g	2	5.8 (105)	10.6 (191)	9.2 (166)	8.1 (146)	
Carpenter and Coustan, 1982	100 g	2	5.3 (95)	10 (180)	8.6 (155)	7.8 (140)	When following a two-step strategy, one abnormal value can be used for diagnosis

Diagnostic Criteria for Gestational Diabetes Mellitus

The diagnosis of GDM on the basis of an OGTT was first defined by O'Sullivan and Mahan in 1964.[7] In their seminal study of 752 women given a 3-hour 100-g OGTT during pregnancy and a further 1013 women followed with periodic OGTTs for up to 8 years, the glucose criteria for the diagnosis of GDM were determined on the basis of a high likelihood (23%) of the mother developing diabetes.

Since that time there have been a number of modifications to the O'Sullivan and Mahan (Table 34.1) criteria, with the National Diabetes Data Group and then the Carpenter and Coustan criteria being modifications of the O'Sullivan and Mahan criteria. The American Diabetes Association uses the same thresholds as Carpenter and Coustan but shortened the test to a 2-hour 75-g OGTT.[8]. More recently, the International Association of Diabetes in Pregnancy Study Groups (IADPSG) has developed new criteria based on the outcomes of the Hyperglycemia and Pregnancy Outcomes (HAPO) study.[9]

The HAPO study evaluated 25,505 women who had a 75-g OGTT at 24 to 32 weeks' gestation.[10] The results of the OGTT were blinded to both the women and caregivers, and therefore there was no treatment for GDM. As a safety net, unblinding and treatment only occurred for women who had a fasting plasma glucose of greater than or equal to 5.9 mmol/L (106 mg/dL) or a 2-hour result greater than or equal to 11.1 mmol/L (200 mg/dL). The investigators examined pregnancy outcomes for women whose OGTTs remained blinded, so that the relationship between the glucose levels and pregnancy outcomes could be established. There was a continuous relationship between the fasting, 1-hour, and 2-hour glucose levels on the OGTT and the four primary outcomes of the study (birth weight >90th percentile, primary cesarean section, clinically detected neonatal hypoglycemia, and cord blood c-peptide level >90th percentile) and no evidence of a threshold effect. Consensus criteria were subsequently developed, with the diagnostic cutoffs determined on the basis of glucose levels at which there was a 1.75 times increase in the odds ratio risk of the four primary endpoints, relative to the mean, at the three time points of the OGTT.[9] With these IADPSG criteria, one abnormality out of a fasting glucose level greater than or equal to 5.1 mmol/L (92 mg/dL), 1-hour glucose level greater than or equal to 10 mmol/L (180 mg/dL), and 2-hour glucose level greater than or equal to 8.5 mmol/L (153 mg/dL) establishes a diagnosis of GDM. These criteria are supported by the WHO and the International Diabetes Federation and are among the criteria accepted by the American Diabetes Association.[3,8] However, they remain contentious, with a National Institutes of Health panel indicating that there is insufficient evidence to support this approach.

Screening for hyperglycemia early in pregnancy is commonly recommended for women at high risk of GDM, and early GDM is associated with worse pregnancy outcomes.[11] If the glycated hemoglobin (HbA1c) or OGTT results performed early in pregnancy are consistent with diagnostic criteria for diabetes outside of pregnancy (i.e., HbA1c ≥6.5% [47 mmol/mol], and/or fasting glucose ≥7.0 mmol/L [126 mg/dL], 2-hour glucose ≥11.1 mmol/L [200 mg/dL]), then it is likely that the woman had preexisting diabetes and would be classified as having ODIP. The diagnosis of early GDM on the basis of the IADPSG criteria, however, is problematic. There are limited data relating the OGTT results at this stage of pregnancy to outcomes, and many centers empirically apply the IADPSG criteria. Moreover, a fasting glucose level of greater than or equal to 5.1 mmol/L (92 mg/dL) in early pregnancy is a poor predictor of the woman meeting diagnostic criteria for GDM at 24 to 38 weeks. The IADPSG has therefore recommended against using a 5.1-mmol/L (92-mg/dL) threshold for the diagnosis of early GDM,[9] and new data have led to dropping of this threshold.[11] There is no consensus as to how to diagnose GDM in early pregnancy. The Treatment of Booking Gestational Diabetes Mellitus trial, which is currently underway, will help to answer this question, as well as the value of early treatment.[12] The American Diabetes Association recommends that women with either impaired fasting glucose (fasting blood glucose ≥5.6 mmol/L [100 mg/dL]) and/or impaired glucose tolerance (2-hour post 75-g glucose ≥7.8 mmol/L [140 mg/dl]) are treated as having hyperglycemia in early pregnancy.

KEY POINTS

- Hyperglycemia in pregnancy includes women with type 1 diabetes mellitus, type 2 diabetes mellitus (T2DM), rare forms of diabetes, diabetes in pregnancy (possible undiagnosed T2DM), and gestational diabetes mellitus (GDM). GDM includes women with mild hyperglycemia from conception and those who develop mild hyperglycemia in the second and third trimesters.

The Incidence of Gestational Diabetes. The incidence of GDM varies depending on the criteria used for diagnosis, the timing of the OGTT, and the population in question. Factors that affect the likelihood of GDM include ethnicity, maternal age and obesity, previous history of GDM or polycystic ovarian syndrome, family history of diabetes, previous macrosomia, and multiple pregnancy. The incidence of GDM has been increasing, rising from 0.3% of pregnancies in the United States on the basis of hospital discharge data in 1979 to 1980 to 5.8% in 2008 to 2010.[13] The incidence in most other countries is higher.

With the lower fasting glucose threshold and the removal of a two-step process for the diagnosis of GDM, the new IADPSG criteria have resulted in more women being diagnosed with GDM. In the multinational population included in the HAPO study,[10] the overall incidence of GDM, diagnosed between 24 and 32 weeks' gestation by the IADPSG criteria, was 17.8%. The WHO estimates that, in 2019, 20 million women worldwide had some form of diabetes in pregnancy, with 84% of these being GDM.

Glucokinase Monogenic Diabetes and Pregnancy

With the low fasting glucose threshold of greater than or equal to 5.1 mmol/L (92 mg/dL) in the IADPSG criteria, glucokinase–maturity onset diabetes of the young (GCK-MODY), which is characterized by a high fasting glucose level, generally between 5.5 and 8.0 mmol/L (99–144 mg/dL), and typically a rise in glucose level on the OGTT of less than 4.6 mmol/L (83 mg/dL), is more likely to be misdiagnosed as GDM upon OGTT. It has been estimated that 0.9% of cases of GDM in fact have GCK-MODY.[14] The detection of GCK-MODY is important because the mother requires treatment only if the fetus does not inherit the genetic mutation. The combination of a fasting glucose greater than or equal to 5.5 mmol/L (99 mg/dL) and a normal body mass index (BMI) has been proposed as a clinical screening criterion to consider genetic testing of the mother for GCK-MODY.[15]

Bariatric Surgery and Gestational Diabetes

The high prevalence of obesity in the community has led to increasing uptake of bariatric surgery. In 2016, it is estimated that 162,969 bariatric surgery operations were performed in the United States.[16] Some 80% of operations were for women, and most women undergoing bariatric surgery are of reproductive age. Both obesity and bariatric surgery have significant ramifications for the incidence, diagnosis, and management of GDM.

Obesity is associated with increased pregnancy risks, including perinatal death, preeclampsia, GDM, and delivery by cesarean section. The literature is discordant as to whether women who have had bariatric surgery have a higher or lower risk of serious adverse pregnancy outcomes, which in part may depend upon the comparator group.[16-18] One metaanalysis showed that, compared with controls matched for presurgery BMI, there are reductions in gestational hypertension, preeclampsia, macrosomia, and cesarean section.[17] The odds ratio for developing GDM was 0.21 (95% confidence interval [CI]: 0.12-0.36). However, when women who had bariatric surgery were compared with control women matched for prepregnancy BMI, there was no difference in GDM. This suggests that the likelihood of adverse outcomes is primarily related to prepregnancy BMI, rather than being an independent effect of the surgery.

Of concern, and relevant to the management of GDM, bariatric surgery is associated with an increase in small for gestational age (SGA) babies and prematurity.[17-19] Although LGA is more commonly associated with GDM, close attention also needs to be paid to intrauterine growth restriction, especially for women who have had bariatric surgery. There are no data regarding how aggressively treatment to glucose targets should be pursued in pregnancies where there is SGA, therefore it would be prudent to take care to avoid overtreatment in this situation.

The greater incidence of SGA may be related to nutritional deficiencies, which have been observed independent of the type of surgery.[18] Micronutrient deficiencies are common following bariatric surgery, and supplementation is necessary during pregnancy.[20] Women with diabetes in pregnancy should generally avoid simple carbohydrates, but an additional reason to do so following bariatric surgery is the risk of dumping syndrome, which can occur in up to 15% of people who undergo bypass operations. Achievement of maternal protein requirements may be more challenging following bypass surgery, and a minimum of 60 g of protein per day has been recommended.[20] Energy requirements need to be individualized on the basis of BMI, gestational weight gain, and physical activity, with close dietetic monitoring being essential.[20]

The Diagnosis of Gestational Diabetes After Bariatric Surgery

The interpretation of the OGTT during pregnancy is difficult for women who have had bariatric surgery. The results are affected by the more rapid transit and absorption of a glucose load, as well as the heightened insulin and incretin response that may occur with late dumping syndrome. It may not be well tolerated, and hypoglycemia can occur. One study found that pregnant women who had gastric bypass surgery had lower fasting glucose levels, higher 1-hour glucose levels, and lower 2-hour glucose levels than BMI-matched controls (4.2 ± 0.4 vs. 4.7 ± 0.5 mmol/L [76 ± 7.2 vs. 85 ± 9.0 mg/dL], 9.5 ± 2.4 vs. 8.2 ± 1.8 mmol/L [171 ± 43 vs. 148 ± 32 mg/dL], and 3.7 ± 1.6 vs. 6.2 ± 1.7 mmol/L [67 ± 29 vs. 112 ± 31 mg/dL], respectively).[21] Half the women who had bypass surgery had hypoglycemia, defined as a serum glucose less than 3.3 mmol/L (60 mg/dL) at 2 hours. Another study using 100-g OGTTs found that hypoglycemia at 2 hours (defined as plasma glucose <3.1 mmol/L [56 mg/dL]) occurred at 2 or 3 hours among 83% of women who had Roux-en-Y gastric bypass, 55% of those who had a sleeve gastrectomy, and even 12% of those who had a gastric band procedure.[22]

Therefore, an OGTT cannot be reliably used to diagnose GDM in women who have had bariatric surgery, although it may be more acceptable for women who have had a gastric band procedure.[20] Recommendations range from undertaking a fasting glucose level and an HbA1c using existing thresholds, to performing capillary glucose day profiles or continuous glucose monitoring.[14,20,23] Although the latter two options appear sensible, as treatment is determined on the basis of glucose profiles, the altered glucose kinetics arising from bariatric surgery may invalidate the usual glucose targets used in pregnancy, and there are no data relating these to pregnancy outcomes.

DIABETES AND PREGNANCY AND THE OFFSPRING

The new IADPSG/WHO criteria for GDM have been developed based upon the potential for perturbations of glycemia to increase fetal growth, particularly adiposity, and fetal insulin secretion, with its effect on fetal growth and the risk of neonatal hypoglycemia. Higher levels of hyperglycemia are associated with greater risks of adverse metabolic outcomes, with additional impacts upon organogenesis.

Congenital Malformations and Early Fetal Loss

Organogenesis occurs in the first 8 weeks of pregnancy, and disruption of this process can lead to congenital malformations. The background rate of congenital malformations is approximately 2% to 3%. Many malformations are lethal, contributing to the background early fetal

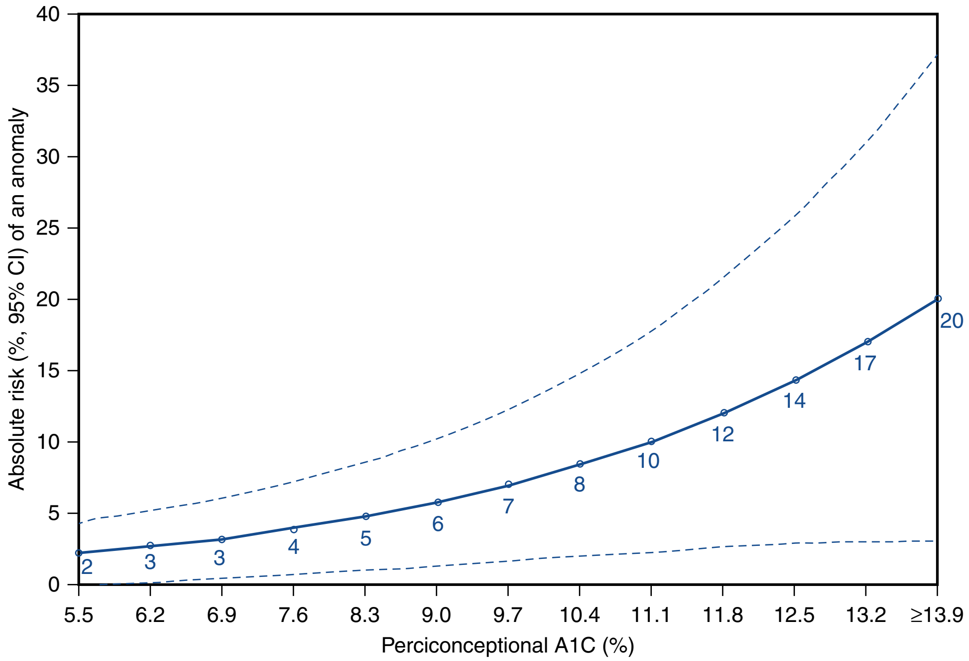

Fig. 34.2 Relationship between glycated hemoglobin in percent and absolute risk of a fetal anomaly. *A1C,* Glycated hemoglobin test; *CI,* confidence interval.

loss. Malformation rates are higher with increasing hyperglycemia as assessed by periconception HbA1c ,as shown in Fig. 34.2.[24]

It is currently unclear whether there is a threshold for increased risk for malformations and spontaneous abortions, previously reported to be around 6.7 to 7.2 mmol/L (120–130 mg/dL). However, malformation rates are also higher among obese women and women with mild hyperglycemia at conception (e.g., with MODY 2).

The more common major malformations include congenital heart defects and neural tube defects (NTDs; including anencephaly and spina bifida). Even when periconception HbA1c is near normal, malformation rates are higher than the background rate. Rates are similar between women with T1DM and T2DM in spite of the generally lower HbA1c at conception among the latter. Other factors likely to contribute to the high malformation rates are obesity, the extent of uptake of prepregnancy folic acid, and possibly antihyperglycemic, antihypertensive, and lipid-lowering medications.

The biology of malformations is largely separate from the biology of macrosomia and the mid to late pregnancy fetal complications. Animal and embryonic stem cell research has revealed several embryonic developmental processes that are affected by maternal hyperglycemia, leading to "diabetic embryopathy."[25] Expression of the glucose transporter 2 (GLUT-2) confers susceptibility to malformations and is important for transporting both glucose and the amino sugar glucosamine. Transient hyperglycemia inhibits Pax3 expression (involved in cell signaling), increases neural tube apoptosis, and increases NTDs. Other mechanisms include oxidative stress, increased generation of free radicals, reduced glucosamine, and disruption of other signaling pathways.

Disturbances of Metabolism and Fetal Growth

Fetal growth is determined by interactions between genetic, maternal, placental, and fetal factors. Maternal size, reflecting some of these factors, and as a composite of both lean mass and adiposity, is a major correlate of overall growth. Nutrient transfer and nutrient use by the fetus are regulated by a variety of maternal, placental, and fetal endocrine mechanisms, including insulin.

Whereas diabetes is defined by random, fasting, and/or postprandial hyperglycemia, other fuels (amino acids, lipids, ketone bodies) are also disturbed. Maternal insulin levels are insufficient in relation to need, ranging from minimal to absent insulin secretory capacity in T1DM to sometimes high levels in, for example, GDM. The original work by Pederson[26] proposed that "maternal hyperglycemia results in fetal hyperglycemia and, hence, hypertrophy of fetal islet tissue with insulin-hypersecretion." Freinkel[1] built upon the Pederson hypothesis, including observations beyond the short-term effects of fetal hyperinsulinemia, with associated macrosomia, neonatal hypoglycemia, polycythemia, and neonatal jaundice, but also long-term effects on behavior (e.g., autism) and long-term metabolic risk (e.g., obesity, dysglycemia). The results from the HAPO study showed a linear relationship between maternal glycemia (from normal to overt diabetes), fetal insulin, and fetal growth.[10] This relationship continues beyond excess adiposity at birth to measures of body composition up to 14 years. Fetal hyperinsulinemia can be great enough to create a maternal-fetal gradient that drives maternal glucose toward the fetus, known as the "fetal-steal" phenomenon.[6] This is postulated to increase fetal adiposity while lowering maternal glucose to levels that falsely reassure treating clinicians.

KEY POINTS

- The Pederson hypothesis proposes that excess maternal glucose crossing the placenta stimulates fetal hyperinsulinemia, leading to macrosomia, neonatal hypoglycemia, polycythemia, and neonatal jaundice. The Hyperglycemia and Adverse Pregnancy Outcomes Study showed a linear relationship between maternal glycemia and fetal insulin and growth.

However, disturbance of the other fuels is also likely to contribute to fetal growth. For example, the elevated maternal FFA and triglyceride concentrations correlate with macrosomia. Maternal triglycerides are hydrolyzed at the placental membrane by placental lipases (e.g., placental LPL) releasing FFAs, which then either diffuse passively or via facilitated placental transport. FFAs can then be directly transported

TABLE 34.2 Institute of Medicine Recommendations for Gestational Weight Gain

Prepregnancy Body Mass Index	Total Weight Gain (kg)	Rate of Weight Gain in 2nd and 3rd Trimester (mean (range) kg/week)
Underweight (<18.5 kg/m^2)	12.5–18	0.51 (0.44–0.58)
Normal weight (18.5–24.9 kg/m^2)	11.5–16	0.42 (0.35–0.50)
Overweight (25.0–29.9 kg/m^2)	7–11.5	0.28 (0.23–0.33)
Obese (≥30.0 kg/m^2)	5–9	0.22 (0.17–0.27)

Calculations assume 0.5–2 kg weight gain in the 1st trimester and presume a linear weight gain throughout the 2nd and 3rd trimesters.

to the fetal circulation from the placenta and metabolised through β-oxidation, with conversion of fatty acyl CoA to acylcarnitine being the rate-limiting step. Alternatively, FFAs can be recoupled with glycerol and stored as triglycerides in the placenta for future transfer to the fetus. However, monitoring and managing triglycerides has not been shown to affect pregnancy outcomes.[27]

More recently, and following the demonstration of heterogeneity in T2DM, there have been a number of publications supporting GDM as also being heterogenous.[28,29] Besides those with overt diabetes in pregnancy, developing T1DM (with antibodies) and monogenic diabetes (including glucokinase mutations), GDM appears to include three other phenotypes: "predominantly insulin-resistant," "predominantly reduced insulin secretion," and mixed insulin resistance/reduced insulin secretion. Women with the maternal insulin-resistant phenotype appear to be more likely to experience complications and adverse pregnancy outcomes (e.g., macrosomia).

Maternal Obesity and the Offspring

The prevalence of obesity and overweight during pregnancy has been growing over the last 30 years. Increasing BMI on entry into pregnancy is associated with increasing risks of GDM, and, even if euglycemic, with greater adiposity and more macrosomia in the offspring. Maternal periconception obesity and GDM development appear to be additive risks for babies being LGA at birth. Excess gestational weight gain is also associated with an increased risk of LGA babies. The Institute of Medicine (IOM)[30] has defined the degree of gestational weight gain expected in each trimester according to maternal BMI, as shown in Table 34.2.

Although excess gestational weight gain is associated with fetal fat accumulation, below the recommended gestational weight gain is associated with reduced fetal growth and a risk of SGA birth weight, with infant catch-up growth and a future risk of obesity, dysglycemia, and cardiovascular disease (the thrifty phenotype).[31] One area of uncertainty is the recommended gestational weight gain for women with a BMI greater than or equal to 30 kg/m^2: whereas the IOM guidelines advise 5 to 9 kg, some clinicians have shown fewer LGA babies and other complications with caloric restriction for a weight gain of 0 to 5 kg. However, this might also be associated with more SGA babies.[32]

MANAGEMENT OF DIABETES IN PREGNANCY

The goal of managing diabetes in pregnancy is to achieve a pregnancy outcome comparable to women without diabetes. Unfortunately, women with all forms of diabetes in pregnancy continue to experience adverse outcomes more frequently than the background population. Women with T1DM are usually aware of at least some of these risks, either before or after conception, and often with a negative "spin" from health professionals or others. Pregnancy is a special time for all women, including women with diabetes, with a range of both hopes and fears. However, women with diabetes have additional pressures, needing to add their diabetes regimen requirements to regular pregnancy-associated actions, all with the knowledge that their pregnancy is at an increased risk of an adverse outcome. As a result, communication of pregnancy risks (with their negative connotations) always needs to be balanced with a positive perspective regarding the potential for a healthy baby, as well as the benefits of pregnancy and of having a family.

Best practice for management is to take a team approach, including an endocrinologist (or internist) experienced in diabetes in pregnancy management, a certified diabetes educator, a dietitian, and an obstetrician or perinatologist. A neonatologist is likely to be needed at birth. Other team members, depending on need, include a social worker and/or a psychologist. Some countries also include a midwife, who may also have certified diabetes educator training, to support women during the pregnancy.

Contraception and Preconception Management

Conception with hyperglycemia is not only associated with an increased risk of malformations and early fetal loss, but also with an increased risk of perinatal mortality and of adverse pregnancy outcomes overall. Women who become pregnant with a high HbA1c usually also exhibit greater hyperglycemia through the pregnancy, which maps to the adverse pregnancy outcomes associated with LGA babies (e.g., shoulder dystocia, birth trauma, and cesarean section) and neonatal hyperinsulinism (neonatal hypoglycemia, neonatal hyperbilirubinemia (jaundice), polycythemia, stillbirth). Beyond managing hyperglycemia, preconception management also includes identifying and replacing any potentially fetoxic medications.

As a result of the need to optimize hyperglycemia before conception, the American Diabetes Association has recommended since 2009 that preconception counseling be given at each clinic visit for all women with diabetes of childbearing age, starting at puberty. This allows information and guidance to be provided regarding contraception choices if sexually active and commencement of prepregnancy or preconception management if pregnancy is actively being considered. On the whole, the preferred contraception choice is one with the highest effectiveness that is least likely to promote weight gain and impact on glycemia. These are essentially the long-acting reversible contraception (LARC) devices, that is an intrauterine contraception system (e.g., Mirena), an intrauterine hormonal contraception device, or a contraception implant (e.g., Implanon; Etonorgestrel). Two injectable preparations are currently marketed, depot-medroxy-progesterone acetate and norethisterone enantate, which are given every 3 and 2 months, respectively. Weight gain and delays in fertility return make injectable contraceptives less preferred options. Combination oral contraceptives containing estrogen and progestin, and progestin-only oral contraceptives are commonly used but are less effective than LARC devices. Any of the hormonal contraceptives can impact on glycemia. Barrier methods assist with sexually transmitted disease control and do reduce pregnancy risk but have a high contraception failure rate. Pregnancy timing methods again have a high failure rate and are not recommended but may be the only choice in those refusing other forms of contraception. Such women (and any pregnancy) would benefit from optimal glycemia management, and potentially folic acid supplementation. In spite of the range and accessibility of different contraception choices, at least 50% of women still report their pregnancies to be unplanned.

Management of glycemia in T1DM, including continuous subcutaneous insulin infusion (CSII) and glucose monitoring technologies, is discussed in detail in Chapter 39. The Continuous Glucose Monitoring in Type 1 Diabetes Pregnancy Trial (CONCEPTT)[33] showed no significant difference among women planning pregnancy between those using continuous glucose monitoring and those using self-blood glucose monitoring. Although human insulins are considered safe at conception and during pregnancy, analog insulins are considered different molecules requiring testing.[34] Insulin lispro, aspart, and detemir have all undergone clinical trials in pregnancy. Fast-acting aspart is considered identical to insulin aspart from a fetotoxicity point of view. Insulin degludec has a trial currently underway in pregnancy. Insulins glargine and glulisine have not yet undergone trials in pregnancy. Insulin glargine does have a number of case series reported that do not suggest teratogenicity or an impact on the fetus.

Although management of T2DM is discussed in Chapter 40, during the prepregnancy period all noninsulin diabetes medications have historically been stopped and an insulin regimen commenced tailored to the glucose profile of the woman. Whereas the noninsulin therapies are not necessarily teratogenic, fetotoxicity is a concern: the newer agents (e.g., SGLT2 inhibitors and GLP1 receptor agonists) have not been tested in pregnancy, and few case series have been reported of conception while using these drugs. One exception is the use of metformin. Using metformin is now known to be safe at the time of conception and through the first trimester.[35] However, some practitioners prefer to avoid metformin, as it is known to cross the placenta. If metformin is used prepregnancy and periconceptually, it is prudent to test for vitamin B_{12} deficiency because this can be associated with metformin use.

Cardiovascular and renal risk factors such as hypertension, dyslipidemia, and microalbuminuria and other comorbidities such as depression are more common among women with T2DM (and T1DM). Several of the drugs used for these conditions are also fetotoxic at different stages during pregnancy, and generally each is suspended during the prepregnancy and antenatal periods if alternatives exist that are as effective. As a result, lipid-lowering agents are usually stopped, and antihypertensive agents are replaced with labetalol, methyldopa, and calcium channel blockers acceptable for use in pregnancy. Antidepressants are decided on a case-by-case basis. The use of angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers is associated with an increased risk of fetal defects in treated women compared with the normotensive population, but not compared with hypertensive women. The use of ACE inhibitors and angiotensin receptor blockers for albuminuria therefore also needs to be discussed on a case-by-case basis, balancing the known benefits from renoprotection with the putative risks from first-trimester exposure to the drugs.[36]

Preconception management includes commencing 5 mg folic acid for use up to 12 weeks' gestation to reduce the risk of neurodevelopmental and cardiac malformations. Women who are not taking folic acid supplements before conception have a 2.2-fold (95% CI: 1.3–3.9) risk of adverse pregnancy outcomes.[37] Although 5 mg daily is recommended, the evidence that a high dose is required to reduce the risk of neurodevelopmental malformations is mixed. There is some evidence to suggest that doses of folic acid above 5 mg should not be used, as they may adversely influence psychomotor development in the future.[38] The recommended maximum daily dose of 5 mg folic acid should therefore include that contained in any other pregnancy supplements being taken (where possible).

The mother herself is at increased risk from changes in insulin sensitivity through the first trimester. Insulin sensitivity increases from approximately gestational week 6 to 7, resulting in an increased risk of severe hypoglycemia in insulin-treated women (mainly T1DM: up to 45% of women).[39] This can lead to loss of consciousness, seizures, and death if no support is available. If driving, there is a risk of a road crash and injury or death. Reducing insulin needs along with severe hypoglycemia may be the first indication of pregnancy in some women. As a result, preconception care needs to optimize diabetes self-management (particularly insulin management and hypoglycemia management) to allow the woman to adjust her own insulin in real time. Training partners to be able to administer glucagon, strictly adhering to driving requirements, and carrying diabetes identification are particularly important during this time. The earliest possible attendance at the diabetes in pregnancy clinic is recommended to help support insulin management during this period. Optimizing glycemia and insulin management often takes time, and contraception is recommended to avoid pregnancy during the preconception glucose stabilization period.

TABLE 34.3 Components of Preconception Care

- Multidisciplinary specialist team
- Screen for complications
- Review medications, ACE inhibitors/A2RB, statins—switch to safe diabetes medications
- Individual counseling re: pregnancy risks/prevention
- Risks of hypoglycemia during pregnancy
- Effective contraception until glycemia and management optimized
- Smoking cessation
- Start 5 mg folic acid
- Self–blood glucose monitoring 4–7 times/day or sensor
- Negotiate targets for HbA1c, blood glucose, time in range—intensification of glycemic management
- Dietitian input
- Immunization and other usual pregnancy preparation
- Promote early booking into diabetes in pregnancy clinic

ACE, Angiotensin-converting enzyme; *A2RB*, angiotensin 2 receptor blockers; *HbA1c*, glycated hemoglobin.

Optimizing glycemia presents further risks for women with preexisting diabetes, particularly if they are relatively hyperglycemic initially. Many women often wish for pregnancy "as soon as possible" for a range of personal and family reasons, leading to rapid improvement in glycemia. This can be associated with acceleration in the development of diabetic eye disease (maculopathy, proliferative retinopathy). Pregnancy itself can be associated with progression in diabetic eye disease,[39] and early attendance at the diabetes in pregnancy clinic also allows early retinal screening to be organized. Screening for microalbuminuria and renal function before pregnancy also allows discussion of pregnancy-related risks. In general, women with chronic kidney disease 3a or worse or significant proteinuria are counseled about antenatal deterioration in renal function and their increased risk of preeclampsia and extreme premature birth.[40] Table 34.3 summarizes the components of preconception care.

The high rates of unplanned pregnancy and pregnancy with suboptimal diabetes management has led to the development of specialized prepregnancy clinics. Attendance at a prepregnancy clinic is associated with a 71% reduction in risk of malformations (risk ratio [RR] 0.29; 95% CI: 0.21–0.40)[41] and a 54% reduction in perinatal mortality (RR 0.46; 95% CI: 0.30–0.73), suggesting that such clinics should be widely available. However, these clinics are more likely to be accessed by women who are already motivated, aware, and accepting that diabetes-related pregnancy risks can be reduced. As a result, a small number of population-based prepregnancy programs have been tested that generally include educational materials provided/sent to the women, educational programs for non–diabetes specialist healthcare providers (e.g., primary care), and prepregnancy clinics.[42] These programs have improved periconceptual glycemia, higher dose folic acid uptake, teratogenic medication avoidance, and early pregnancy clinic attendance.

KEY POINTS

- Maternal hyperglycemia at conception correlates with increasing fetal malformations. Attending prepregnancy clinics with counseling and education, optimizing glucose control, avoiding fetotoxic drugs, and taking 5 mg folate daily are associated with a 71% reduction in malformations and a 54% reduction in perinatal mortality.

Management of Type 1 Diabetes Mellitus in Pregnancy

Once a woman with T1DM has conceived, there is an urgency warranting intensive management, including evaluation of the existing maternal and fetal risks. Risk assessment for the endocrinologist includes a general medical review including weight, blood pressure, full foot examination and ensuring that ophthalmological examination has occurred. Renal function assessment (serum creatinine, estimated glomerular filtration rate, and microalbuminuria/proteinuria screening) and, when appropriate, cardiovascular assessment should occur. Glycemia history including diabetic ketoacidosis, weight management and particularly hypoglycemia history need to be considered. Hypoglycemia assessment includes the assessment of hypoglycemia awareness using a standard approach (e.g., Gold score) and potentially whether autonomic neuropathy is present (e.g., lying/standing blood pressure). Understanding the hypoglycemia risk is of particular importance in the second half of the first trimester, when insulin sensitivity increases, and the rate of hypoglycemia, and particularly life-threatening severe hypoglycemia, can increase. Counseling relating to the personal risks of pregnancy, including miscarriage, need to be undertaken sensitively within a positive and optimistic outlook. Commencing intensive glucose management and ensuring that folic acid (5 mg) is in place up to gestational week 12 (if not already in place) are part of this initial review.

Maximizing self-management skills is clearly particularly important during pregnancy, and this will have hopefully occurred before conception, including carbohydrate counting, quantitative approaches to mild hypoglycemia, glucagon use (for the partner), driving requirements, sick-day planning with blood ketone meter use, insulin site rotation, and fresh needle use. Self–blood glucose monitoring has been revolutionized by the development of continuous glucose monitoring systems (CGMSs) and flash glucose monitoring systems (FGMSs), also known as "sensors." Insulin management has similarly been evolving following the introduction of CSII technology, "smart" meters (with their increasing replacement by "apps"), and "closed loop" technology (where the CSII talks to the sensor).

Many of those with T1DM have a range of psychological, financial, social, and medical barriers to care and self-care, and these need to be carefully assessed at this point and throughout pregnancy. Pregnancy, and the need to manage glycemia tightly on a day-by-day basis to protect the growing fetus, places a major personal burden on many women. Some women may need to adapt their working life to adjust to the time demands of managing their diabetes in pregnancy. A small number of women may need to be hospitalized at some point during their pregnancy if it becomes clear that glycemia management needs a major correction, if there are major psychosocial barriers to self-management (e.g., family or work), or if there is a risk of severe hypoglycemia (or diabetic ketoacidosis). Naturally, such hospitalization and inpatient stabilization occurs in a dramatically different nondomestic, less mobile environment, with hypoglycemia risks (or reversion to prior self-management approaches) on discharge and reverting back to life at home.

Following conception, insulin needs vary weekly, as shown in Fig. 34.3.[43] Besides maximizing self-management skills, addressing this variation requires regular clinical reviews to ensure that proactive insulin regimen changes are made. This is usually achieved by a mix of face-to-face, online, and telephone consultations to be able to interpret the glycemic pattern, including any aberrations as a result of lifestyle events.

Fig. 34.3, using data from women with T1DM in pregnancy, shows the initial increase in insulin requirements as the glucose increases up to gestational week 7, then a decrease up to gestational week 12, slowly rising glucose to gestational week 30, and then a decrease after this point.

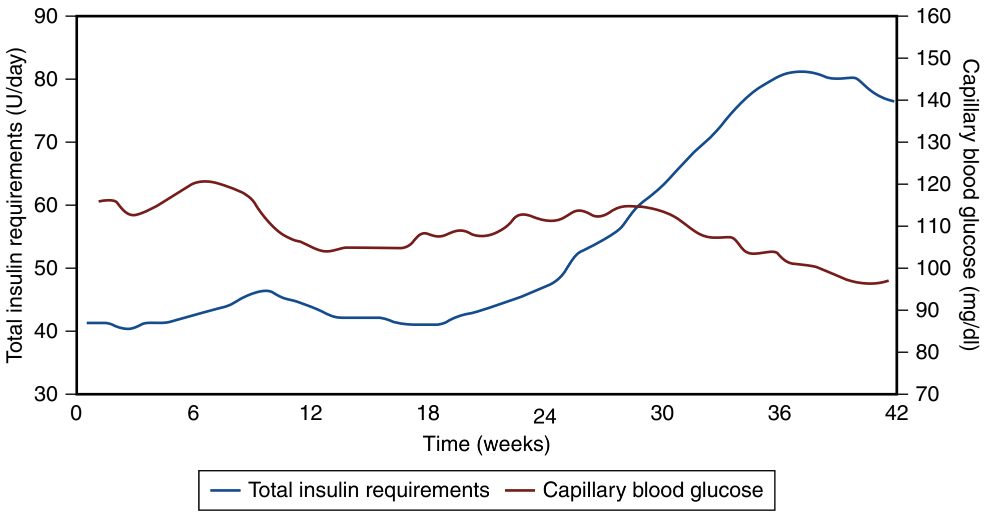

Fig. 34.3 Changes in insulin and glucose during pregnancy among women with type 1 diabetes. (Data from García-Patterson A, Gich I, Amini SB, et al. Insulin requirements throughout pregnancy in women with type 1 diabetes mellitus: three changes of direction. *Diabetologia*. 2010;53:446–451.)

Insulin management is tailored to glucose monitoring, although gestational weight gain above the IOM recommendations can indicate overinsulinization, along with the associated hypoglycemia and/or additional food consumption. Weight management needs to be monitored closely and, where necessary, discussed. Psychological factors, including fear of hypoglycemia, can impact on achievement of glycemia goals associated with optimal pregnancy outcomes.

Glycemia Monitoring

Traditionally (after the era of testing for glycosuria), self–blood glucose monitoring has been undertaken using a fingerprick to access capillary blood and a strip with a reagent to metabolize glucose from the sample and create an electric current measured by a blood glucose meter. This provided much more useful, and real-time, data than urine testing. Daily self-blood glucose monitoring during pregnancy for women with T1DM is recommended, as for nonpregnant adults, fasting (or at breakfast time for those who do not eat breakfast) to identify the effect of overnight insulin treatment, before meals to assess hypoglycemia risk, and before bed. However, during pregnancy, postprandial glycemic spikes can stimulate fetal hyperinsulinism and associated fetal adiposity, with their associated adverse pregnancy outcomes. As a result, postprandial monitoring is particularly important during pregnancy. Recommended glycemic targets are shown in Table 34.4 but need to be individualized with regards to hypoglycemia patterns, hypoglycemia unawareness, and physical activity and with an understanding of mothers' perspectives on their hypoglycemia risk.

In the first trimester, the rapidly changing glucose can pose challenges, and the initial upward glucose direction can be the first indication of pregnancy. However, as this drops after gestational weeks 6 to 7, and the hypoglycemia risk increases, it can be prudent to set higher preprandial targets (e.g., 5.5 mmol/L [99 mg/dL] or even up to 6.0 mmol/L [108 mg/dL]). There is little evidence that a slightly higher target in the first trimester is harmful and some evidence that hypoglycemia during the first trimester may be associated with an increased risk of macrosomia.[44] Another important glycemic pattern to actively seek is the overnight glucose. Besides its own intrinsic life-threatening risk, repeated nocturnal hypoglycemia can blunt hypoglycemia awareness and is possibly associated with fetal fuel undersupply and SGA babies. As symptoms are unreliable, nocturnal hypoglycemia may warrant self–blood glucose monitoring at 3:00 AM, the glucose nadir. The reasons for the hypoglycemia can be identified by reviewing the glucose pattern and insulin therapy among the evening meal, before bed, and 3:00 AM. The 3:00-AM test also allows the dawn phenomenon to be identified where this occurs. This is a critical piece of information, as it prevents an excess increase in overnight background/basal insulin based upon the before-breakfast glucose test results. Such women often require a small bolus quick-acting dose (without food) at approximately 4:00 AM (tailored to the individual) to prevent the rise. "Testing" at 3:00 AM is easily achievable using a sensor, of course.

TABLE 34.4 Recommended Glucose Targets During Pregnancy

	Preconception[a]	Pregnancy[a]
Fasting and premeal: mmol/L (mg/dL)	<6.0 (≤108)	<5.3 (≤95)
1 hour postmeal: mmol/L (mg/dL)	<8.5 (≤153)	<7.8 (≤140)
2 hours postmeal: mmol/L (mg/dL)	<7.5 (≤135)	<6.7 (≤120)

[a] If these targets can be safely achieved without causing significant hypoglycemia.

During pregnancy, when glucose targets are much tighter than outside pregnancy to protect the fetus, and normal fasting glucose is lower, meter accuracy and precision are of particular importance. However, many glucose meters in current use have a range of systematic and nonsystematic factors (e.g., hematocrit) that can lead to under- and overreading and greater variation.[45] Table 34.5 shows the factors that should be considered when deciding on which meter to use during pregnancy. Some meters ("smart meters") have inbuilt algorithms to provide advice on how much insulin to give based upon the amount of carbohydrate entered and the glucose level, with preentered carbohydrate ratio and correction factor along with insulin action. Such meters are now being replaced by apps that can undertake these tasks from a mobile phone.

There are several criticisms of self–blood glucose monitoring using fingersticks. In pregnancy, the ongoing variation in glycemia, tight glucose targets, and importance of postprandial hyperglycemia make the intermittent nature of self–blood glucose monitoring a suboptimal approach to managing T1DM. CGMS and FGMS glucose monitoring measure the glucose in the interstitial fluid, so there is a lag of 10 to 15 minutes compared with capillary blood glucose monitoring. Although CGMS measures the glucose frequently and continuously transmits the data to a receiver, FGMS measures the glucose every minute and stores the data for up to 8 hours. FGMS then picks up the data when a reader is passed over the sensor. CGMS may require calibrating, depending on the manufacturer. FGMSs are currently worn on the posterior aspect of the upper arm, and CGMSs usually on the abdomen (but there are other sites). CGMS and FGMS can provide falsely low readings, and the lag may mean that hypoglycemia is not detected. Thus, it is recommended that a confirmatory fingerprick test take place if hypoglycemia is reported or if there is discordance between the expected and reported glucose (e.g., with hypoglycemia symptoms). A confirmatory blood glucose is recommended before changing the insulin regimen. Several systems recommend a test before driving. CGMS and FGMS can provide alarms when the glucose is low or high, allowing rectifying action to be initiated, thereby avoiding extreme glycemic values.

CGMS and FGMS provide a great deal of data, the interpretation of which can be challenging. There may be an overall pattern to guide changes in insulin therapy, although confirmatory fingerprick testing may still be needed, particularly at night. The reports can provide "wear time," which should be greater than 70% to be considered reliable. This can be a problem during pregnancy, with the growing abdominal circumference. The glucose management index provides an estimated HbA1c, and the coefficient of variation is one measure of glycemic variability (should be <36%). Aggregate and daily patterns will show times of hypo- and hyperglycemia. The target time in range (TIR) in pregnancy[46] is greater than 70%, but at a lower target range than for nonpregnant adults at between 3.5 and 7.8 mmol/L (63–140 mg/dL), with less than 4% below 3.5 mmol/L (63 mg/dL) and less than 25% above 7.8 mmol/L (140 mg/dL). For women who are pregnant, TIR is insufficient alone, as the preprandial and postprandial glucose targets still need to be followed to minimize excess fetal fuel supply (e.g., a fasting glucose of 5.3 mmol/L [95 mg/dL] at

TABLE 34.5 Characteristics of Preferred Blood Glucose Meters During Pregnancy

- Lowest deviation possible (i.e., a total error <5% with an imprecision (coefficient of variation) <2%).
- Takes into account the potential influence of hematocrit changes on the meter values.
- Automatic measurement and correction for hematocrit changes.

TABLE 34.6 **Current Safety Status of the Different Types of Insulins During Pregnancy**

Insulin	Insulin type	FDA Pregnancy Category	RCT Findings Versus Human
Regular U-100	Short-acting	B	-
Regular U-500	Short-acting, concentrated	B	-
Lispro U-100 and U-200	Rapid-acting	B	Vs. regular—no difference
Aspart	Rapid-acting	B	Vs. regular—no difference
Fast-acting Aspart	Very fast-acting	B	As per Aspart
Glulisine	Rapid-acting	C	No RCT in pregnancy
NPH	Intermediate-acting	B	-
Detemir	Long-acting	B	RCT vs. NPH—no difference
Glargine U-100	Long-acting	C	No RCT in pregnancy
Glargine U-200	Long-acting	C	No RCT in pregnancy
Degludec U-100 and U-200	Long-acting	C	RCT underway
Inhaled human insulin	Inhaled	C	No data

FDA, US Food and Drug Administration; *NPH*, neutral protamine Hagedorn; *RCT*, randomized controlled trial.

Category A: Adequate and well-controlled studies have failed to demonstrate a risk to the fetus in the first trimester of pregnancy (and there is no evidence of risk in later trimesters).

Category B: Animal reproduction studies have failed to demonstrate a risk to the fetus, and there are no adequate and well-controlled studies in pregnant women.

Category C: Animal reproduction studies have shown an adverse effect on the fetus, and there are no adequate and well-controlled studies in humans, but potential benefits may warrant use of the drug in pregnant women despite potential risks.

24 to 28 weeks' gestation was associated with a 2-fold risk of adverse outcomes[10]). Data from CGMS/FGMS can also be used in an app to guide insulin bolus calculations, although a fingerprick test is recommended where there is discordance with expectations or, for example, to change dosage.

Although one Danish randomized controlled trial (RCT) did not show benefit from CGMS,[47] a multicenter RCT, CONCEPTT, showed reduced rates of LGA infants (odds ratio [OR] 0.51; 95% CI: 0.28–0.90), neonatal intensive care admissions lasting 24 hours or more (OR 0.48; 95% CI: 0.26–0.86), and neonatal hypoglycemia (OR 0.45; 95% CI: 0.22–0.89).[33] CONCEPTT also showed increased TIR. Pregnancy outcomes, while improved, were not normalized with CGMS.

Whereas HbA1c can provide an overall guide to glycemia, as in nonpregnant adults, increased erythrocyte turnover lowers the red cell glycation time, leading to a lower target (often taken as 6.0% (42 mmol/mol), but suggested to be 5.6% (37 mmol/mol) in at least one study[48]). HbA1c does not provide the granularity of glycemic variation required to manage diabetes in pregnancy, but a measurement in each trimester is useful for an overall longer-term benchmark for use in consultations.

Diet and Physical Activity

In general, women with T1DM follow the dietary, physical activity, and weight gain recommendations for women without diabetes, with a number of caveats relating to their personal glycemic response to food or to physical activity. Foods with a lower glycemic index (GI) are helpful.[49] In the first trimester, and sometimes into the early second trimester, additional snacks may be required to avoid hypoglycemia between meals, depending on the insulin regimen in place. Weight gain in the first trimester is to be avoided, though, as per the IOM guidelines. As insulin resistance increases, the carbohydrate content of meals may need to be limited (e.g., to 50 g) to avoid a postprandial spike. Mornings are often associated with particularly high postprandial spikes, and some services reduce the morning carbohydrate content to 20 to 30 g in some individuals. The postprandial spike can be mitigated to some extent by increasing the time between insulin administration and the meal, as well as by postprandial physical activity,[50] but caution is needed to avoid hypoglycemia during this time. It is thought to be important to maintain carbohydrate intake and minimize ketogenesis following the demonstration that maternal antenatal 3-hydroxybutyrate concentrations correlate negatively with cognitive function in the offspring.[51]

Hypoglycemia risk in relation to physical activity may be heightened during the first trimester but reduced during the third trimester, when insulin resistance is at its greatest. Reduction in postprandial hyperglycemia can be effected through exercise (e.g., walking after meals). Foot care and footwear remain particularly important for those women with neuropathy.

Insulin Management

Women with T1DM will enter pregnancy receiving either a multiple dose insulin (MDI) regimen, involving background and prandial insulin, or CSII. Human insulin is considered safe during pregnancy, but insulin analogs vary in the level of safety data available. Table 34.6 summarizes the current status of the use of the different types of insulins during pregnancy.

Although insulin management is covered in detail in Chapter 39, during pregnancy, insulin dosing is not only different for each individual, but also varies in the setting of changing physiological insulin needs (periods of insulin sensitivity and increasing insulin resistance), varying degrees of nausea (nil to hyperemesis gravidarum over different periods of time), different degrees of physical activity (generally decreasing in the third trimester), gestational weight gain, and individual responses and choices of food and physical activity. This is further affected by factors that influence insulin absorption outside of pregnancy, including lipohypertrophy, injection technique, injection site, and prandial insulin dose (particularly as the dose can, for example, triple by the third trimester).[52] One further factor of importance during pregnancy is the potential for worsening dawn phenomenon. Although the dawn phenomenon (a transient rise in blood glucose between 4:00 AM and 6:00 AM) is not important among pregnant women with normal glucose tolerance,[53] it creates additional challenges for many pregnant women with T1DM.[54] As an example, in one Danish study, although the carbohydrate-to-insulin ratio was reduced from median 12 (range 4–20) at 8 weeks' gestation to 3 (range 2–10) grams carbohydrate per unit insulin at 33 weeks' gestation, ratios only declined to 6 (range 2–13) at lunchtime and 4 (range 2–10) at dinner.[55] Over the same period, basal insulin increased by from 0.8 (range 0.5–2.2) to 1.2 (range 0.6–2.5) IU/h at 5:00 AM and from 1.0 (range 0.6–1.5) to 1.3 (range 0.2–2.3) IU/h at 5:00 PM.

Dealing with this variation and increased insulin resistance in the morning requires substantial work by the woman. CGMS and FGMS can assist with identifying the times when glucose is high and low. A consistently high morning glucose may reflect the dawn phenomenon, nocturnal hypoglycemia, and/or insufficient nocturnal insulin dosing. Where CGMS or FGMS are unavailable, it is usually wise for the woman to at least intermittently test at 3:00 AM before the usual dawn rise to assess the changing pattern. Dealing with the dawn phenomenon, if sufficient to necessitate treatment, requires a bolus without carbohydrate cover (sometimes a difficult ask of women with, for example, hypoglycemia fear). This involves identifying the time that the glucose rises and injecting quick-acting insulin 0 to 10 minutes beforehand. When women are using CSII, this can be preprogrammed with an increase in the hourly basal rate. If MDI is being used, then this requires waking up and injecting (e.g., at 4:00 AM) and hopefully returning to sleep.

Although CGMS has been shown to improve glycemia and improve pregnancy outcomes in one large study, findings from studies of CSII suggest little benefit during pregnancy. Theoretically, CSII should provide many benefits for self-management, including the Bolus Wizard to avoid guessing bolus doses, the incorporation of active insulin time to reduce the risk of stacking (where several insulin boluses are acting at the same time), and the use of temporary basal rates to adjust infusion rates with exercise or when it is unclear whether needs have changed or not (a major issue during pregnancy!). However, a systematic review of RCTs of CSII versus MDI performed up to 2016 showed no clear differences, with a suggestion that mean birth weight might be higher with CSII.[56] A systematic review and metaanalysis of cohort studies showed no difference in pregnancy outcomes and overall no difference in HbA1c.[57] However, technology continues to develop, and CSII continues to improve, with additional functionalities. CSII can be controlled through a handset or through a mobile phone. Tubing is either required separately or as part of a discardable device (a patch pump). The rapid changes in pump technology pose problems for trialists, as the technologies will often be out of date by the time a trial is completed and analyzed. Furthermore, trials involving CSII alone may already be redundant. CGMS can be linked with CSII to create a hybrid closed-loop system that allows real-time communication and the use of algorithms, with the glucose level and its trends automatically adjusting basal inulin delivery without user input.[58] Overnight glycemia can be stabilized, insulin delivery can be suspended to avoid impending hypoglycemia, and alarms allow user action at high or low glucose thresholds. Glucose-level predictive algorithms can allow user action well before hypoglycemia becomes severe. There remain a number of challenges with these systems, including dependency on the sensor, which can read low, and user exhaustion resulting in the user ignoring or switching off alarms. The tight glucose targets during pregnancy currently remain a challenge for these systems, with hyperglycemic rebound after basal insulin suspension and automated glycemic targets well above the pregnancy glucose targets. However, new models are emerging to address these issues.

Management of Type 2 Diabetes and Overt Diabetes in Pregnancy

Women with T2DM who become pregnant and those considered to have had undiagnosed (likely T2DM) diabetes at conception (overt diabetes in pregnancy) face overlapping but different challenges to those with T1DM. Women with overt diabetes in pregnancy are managed as if they have T2DM in pregnancy. Key actions are:

- Urgent commencement of intensive management
- Risk assessment including risk factor/complication review, (e.g., eyes, feet, renal, cardiovascular disease)
- Glycemia assessment including hypoglycemia risk (potentially suggestive of misclassified T1DM, monogenic or secondary diabetes)
- Medication history, particularly antidiabetes medications besides metformin, antihypertensive, and lipid treatment
- Counseling regarding the personal risks of pregnancy, including miscarriage
- If treated with metformin, discussion of safety in the first trimester, transplacental passage, antenatal balance between reduced cesarean section and weight gain, but increased risk of SGA and uncertain long-term risks
- Initiation of self–blood glucose monitoring if not yet in place (CGMS/FGMS if possible and affordable)
- Folic acid (5 mg) if not in place up to gestational week 12
- Aspirin 100 to150 mg from week 8 to 16
- Cessation of oral antidiabetes medications/GLP1 receptor agonist, commencement of insulin therapy (including education regarding driving), but continuation of metformin unless there is concern about it crossing the placenta
- Switching from antihypertensives to pregnancy-safe drugs (methyldopa, labetalol, nifedipine)
- Stopping lipid-lowering medications

The management of women with T2DM includes women commencing pregnancy well-managed with diet and physical activity alone and no comorbidities, all the way to women with severe insulin resistance, level 3 obesity, hypertension, dyslipidemia, and other comorbidities (e.g., microvascular disease). Beyond lifestyle, glucose monitoring, regular review, and counseling, treatment includes metformin and/or insulin therapy. Metformin safety during pregnancies among women with T2DM was demonstrated by the Metformin in Women with Type 2 Diabetes in Pregnancy RCT of adding metformin treatment up to 2 g/day (if tolerated) among insulin-treated pregnant women with T2DM.[59] Metformin (vs. placebo)–treated women achieved lower HbA1c at 34 weeks' gestation (5.9% vs. 6.1% [41.0 mmol/mol vs. 43.2 mmol/mol]) and mean glucose (109 mg/dL vs. 113 mg/dL [6.05 mmol/L vs. 6.27 mmol/L]), required less insulin (1.1 units/kg/day vs. 1.5 units/kg/day) and gained less weight (7.2 kg vs. 9.0 kg). Although most women birthed by cesarean section, the proportion was lower among metformin-treated women (53% vs. 63%). Babies were less fat, with fewer above the 97th centile (9% vs. 15%) and over 4000 g at birth (12% vs. 19%). However, the frequency of SGA babies was greater (13% vs. 7%), albeit with no excess neonatal intensive care unit admission, highlighting a potential future risk of metabolic syndrome components in the offspring.[31] As a result of this putative long-term risk, in association with metformin crossing the placenta and no long-term studies in T2DM, there remains caution over metformin use. However, among women with T2DM in pregnancy, these theoretical risks need to be weighed against the actual benefits of reduced cesarean section and less macrosomia.

Where metformin is not used, and glucose targets are exceeded, insulin management follows a similar pattern to that in T1DM, although generally a fixed dose insulin regimen rather than carbohydrate ratios is used. Women with T2DM usually have sufficient insulin secretory capacity to buffer some variations in glucose. Hypoglycemia is less of a risk and, when it occurs, is less likely to be severe. However, some women may have less insulin secretory reserve and may be more insulin-sensitive than others. It may be helpful to assess diabetes type among these women (e.g., T1DM), as the usual phenotype of T2DM is one of underlying increased insulin resistance accompanying the insulin insufficiency.

Insulin resistance can become an increasing problem, necessitating large amounts of insulin. Although metformin can help reduce insulin requirements in T2DM[59] (e.g., from 155.29 ± 134.01 units/day to 109.76±105.1 units/day), the insulin dose remains sizeable, and the broad variance reflects some women needing a substantially higher dose. CSII has been used to overcome insulin resistance among women requiring more than 100 units insulin/day. In one study, the median insulin dose was 246 (range 116–501) units/day or 2.68 units/kg booking (first antenatal) weight.[60] Glycemia improved among 79% of the women within 1 to 2 weeks. Another option is to use U-500 insulin for the meal boluses, which reduces the surface area and increases the speed of absorption.

Management of Diabetes Complications in Pregnancy

The White classification of diabetes in pregnancy,[61] based on diabetes duration and the presence of different diabetes complications, is no longer useful in guiding assessment of diabetes in pregnancy risk or management. The focus is now on assessing glycemia and blood pressure before and during pregnancy, alongside detailed assessment of acute (hypoglycemia, diabetic ketoacidosis) and chronic (diabetic nephropathy, retinopathy/maculopathy, ischemic heart disease, neuropathy including autonomic neuropathy, and diabetic foot disease) complications.

Nephropathy. Pregnancy is a time when glomerular filtration rate normally increases by 50%, and, among women with preexisting diabetes and renal disease, both the kidneys and the fetus can be compromised. Women with existing known diabetic nephropathy will usually have been treated before pregnancy with renin-angiotensin system (RAS) blockade agents (ACE inhibitors or angiotensin receptor blockers). There is some evidence that RAS blockade agents are teratogenic, with retrospective cohort studies reporting an increased risk of fetal defects in women on RAS blockade compared with the normotensive population (RR 3.7; 95% CI: 1.8–7.3[62] and OR 1.5; 95% CI: 1.1–2.6[63]). However, no difference in rates was shown compared with other hypertensive women (RR 0.8; 95% CI: 0.7–1.1[64] and OR 1.1; 95% CI: 0.6–1.9[63]). Hence currently, clinical judgment is required to determine whether the benefits of RAS blockade outweigh the possible harm in the first trimester. Otherwise, RAS blockade agents are contraindicated in the second and third trimester, as they increase the risk of fetal anuria, oligohydramnios, and renal tubule dysplasia. For those without known nephropathy, urinalysis is usually performed at the initial visit (and at each subsequent visit to screen for preeclampsia). Where proteinuria is detected (urine albumin-to-creatinine ratio >35 mg/mmol), a monthly urinary protein:creatinine ratio can be used to monitor worsening renal function. Women in the nephrotic range might benefit from thromboprophylaxis.

Pregnant women with diabetes, microalbuminuria, and normal renal function are unlikely to experience loss of kidney function.[65] Conversely, women with chronic kidney disease 3a (glomerular filtration rate <60 mL/min) and/or proteinuria great than or equal to 3 g/24 hours at the beginning of pregnancy are at approximately 40% risk of permanent kidney damage. Renal function can deteriorate significantly during pregnancy, and a nephrologist review is likely to be required among these women or if renal function deteriorates. Some women do require dialysis. Blood pressure management is important, but the optimal blood pressure is unclear, with some recommending 135/85 mm Hg.[66]

Pregnancy outcomes have improved but remain a concern, with fetal survival rates of 89% to 100%. There are increased rates of preeclampsia (15%–55%), cesarean section (70%–82%), intrauterine growth restriction (11%–21%), and premature delivery (16%–31% before gestational week 35).[65]

Retinopathy. Diabetic retinopathy (DR) has been reported to be present in 34% to 72% of pregnant women with T1DM and 14% of women with T2DM.[39] Treatment for proliferative DR and diabetic macular edema (DME) will preferably occur preconception, and glycemia should be optimized before and during pregnancy. Progression of DR during pregnancy occurs at about double the rate as in nonpregnant women.[66] Progression is more likely with longer diabetes duration, existing DR at the beginning of pregnancy, poor glycemic control, and elevated blood pressure. Patients with T2DM might have a lower risk of DR progression, but for both T1DM and T2DM, rapid improvement in glycemia is associated with accelerated development of DR. As a result of the increased risk, women with preexisting diabetes (previously diagnosed or otherwise) undergo retinal review in the first trimester, at the end of the second trimester, and, if considered at risk of progression, during the third trimester. Fluorescein does cross the placenta and is not recommended. If retinopathy is present, monitoring is likely to be more frequent. Proliferative DR is treated with panretinal photocoagulation. DME can be sight-threatening, and of course is not generally amenable to panretinal photocoagulation, but the new anti–vascular endothelial growth factor drugs remain contraindicated during pregnancy (and probably breastfeeding). Intravitreal triamcinolone and systemic steroids (e.g., dexamethasone) have been used previously with success and no side effects. DR is no longer considered a contraindication to vaginal birth, although there remains a theoretical risk if severe DR is present, and this should be discussed with the woman. Retinopathy can regress postpartum.

Coronary Artery Disease. Preexisting coronary artery disease remains rare among women with diabetes who become pregnant. Nevertheless, enquiry regarding cardiac disease risk factors and symptoms remains important both prepregnancy and when pregnant. In terms of treatment for acute events, pregnant women have usually been excluded from trials, and hence the safety of the current acute coronary artery disease management regimens during pregnancy among women with diabetes is unclear. In a 2019 review of 125 women with manifestations of coronary artery disease, 18% had diabetes (including GDM).[67] Maternal mortality was 2%, mean gestation at birth was 37 weeks, premature birth occurred in 32%, 50% had a cesarean delivery, and neonatal death occurred in 4%.

Neuropathy. Peripheral neuropathy and diabetic feet remain a risk during pregnancy and may be exacerbated by edema and the increasing weight. As a result, usual foot care recommendations should be followed. Of more concern is autonomic neuropathy including orthostatic hypotension, gastroparesis, and impaired hypoglycemia awareness. Orthostatic hypotension, aggravated by the pregnancy-related fall in systemic vascular resistance, can almost immobilize a small number of women, particularly in association with hyperemesis and dehydration. Hyperemesis can be worse with gastroparesis and, if severe, gastroparesis can be a relative contraindication to pregnancy. Use of prokinetic and other drugs needs to be balanced with their potential risks to the fetus if they cross the placenta.

Management of Gestational Diabetes Mellitus

The management of GDM is based upon the two major RCTs performed to date: (1) the Australian Carbohydrate Intolerance Study in Pregnant Women RCT, which showed a reduction in the primary perinatal composite outcome consisting of neonatal death, shoulder dystocia, bone fracture, and nerve palsy and (2) the Maternal-Fetal

Medicine Units Network RCT, which showed that GDM treatment was associated with a significantly decreased risk of LGA, shoulder dystocia, cesarean section, gestational hypertension, and preeclampsia.[68,69]

KEY POINTS

- The two major randomized controlled trials showing reductions in adverse pregnancy outcomes were the Australian Carbohydrate Intolerance Study in Pregnant Women study and the Maternal-Fetal Medicine Units Network study.

Once GDM has been diagnosed, its management involves counseling/education regarding the pregnancy risks, physical activity advice, medical nutrition therapy, weight management, self–blood glucose monitoring, and obstetric monitoring, and, if the glucose targets in Table 34.4 are exceeded, pharmacotherapy is commenced. Weight management follows IOM guidelines (Table 34.2). At least 30 minutes per day of moderate-intensity exercise is recommended,[70] with several goals beyond the holistic needs of pregnancy, including improving fasting and postprandial glucose and reducing the need for insulin or reducing the dose of insulin. Some studies have shown that physical activity intervention among women with GDM decreases gestational weight gain, and births are less likely to be complicated by macrosomia, cesarean section, preterm birth, and SGA. Recent studies show that sedentary behavior (any waking behavior characterized by an energy expenditure ≤1.5 metabolic equivalents while in a sitting or reclining posture) is associated with worse neonatal outcomes, and advice should therefore include approaches to increase movement overall.

RCTs to date have shown that dietary modification among women with GDM is associated with lower fasting (−4.07 mg/dL [95% CI: −7.58, −0.57]) (−0.2 mmol/L [95% CI: −0.4, −0.03]; *P* = .02) and postprandial (−7.78 mg/dL [95% CI: −12.27, −3.29] −0.4 mmol/l [95% CI: −0.7, −0.2]; *P* = .0007) glucose, as well as a 35% (95% CI: 12-53; *P* = .006) lower need for medication.[71] Dietary modification was also associated with less macrosomia (RR 0.49 [95% CI: 0.27−0.88]; *P* = .02). Different diets have been used, including the Mediterranean diet, low-GI diet, a diet with increased or decreased carbohydrate content, and diets with modifications of fat or protein quality or quantity. Energy restriction and low-carbohydrate diets associated with gestational weight loss are a concern in view of the association with lower fetal lean mass and, potentially, long-term metabolic disease.[31] A metaanalysis of the low-GI diet showed no benefits in terms of neonatal outcomes.[72]

Insulin therapy has traditionally been the main pharmacotherapy for treating GDM when glucose thresholds are exceeded. The usual approach is to use self–blood glucose monitoring to identify where the glycemic thresholds are exceeded and then to use quick-acting insulin analogs such as aspart or lispro (see Table 34.6), injected 15 to 20 minutes before a meal to reduce each postprandial glucose peak, and/or neutral protamine Hagedorn (NPH) insulin injected before bed to reduce the overnight/fasting glucose. Detemir in pregnancy is noninferior to NPH insulin and is particularly useful for women who are more susceptible to nocturnal hypoglycemia using NPH insulin. Reducing glucose among some women with GDM can be challenging, requiring large amounts of insulin. Strategies can include increasing the time between quick-acting insulin administration and meals, spreading the carbohydrate load (reducing carbohydrates in each meal, particularly breakfast), adding NPH in the morning, using concentrated insulins (e.g., U-500), and using CSII. CGMS/FGMS are also being used to assist with management.

Many women would prefer not to inject insulin, with its risks of hypoglycemia, weight gain, discomfort, and complexity. As a result, oral therapies have been trialed as more convenient and cheaper approaches to GDM management. The medications tested, metformin and glyburide (glibenclamide), can both lower blood glucose and allow insulin to be avoided in 50% or more women. Dosage is not as flexible, but for many women that dosage does not need to be adjusted to adapt to varying insulin secretory function. Beyond the side effects of these drugs described in Chapter 40, the major concern is that both cross the placenta and can potentially impact on the fetus. Glyburide is generally no longer recommended, owing to its association with higher fetal birth weight with more frequent macrosomia and neonatal hypoglycemia compared with insulin.[73] This may be the result of a direct effect on the fetal β cells inducing hyperinsulinemia. There are also no long-term follow-up studies of offspring with intrauterine exposure to glyburide. Compared with insulin use, metformin has been shown to result in less maternal gestational weight gain, lower postprandial glucose, less pregnancy-induced hypertension and less severe neonatal hypoglycemia.[73] Metformin is also preferred by women. However, a high proportion of metformin crosses the placenta, and follow-up studies of trial participants treated with metformin from the end of the second trimester have variably shown associations with adiposity and possibly hyperglycemia.[35] As a result, it is important for women to be given information regarding, and have explained, the uncertainties about any long-term consequences of metformin use, balancing this with the benefits shown in trials. If metformin is used, then it can be started with 500 mg once per day and increased by 500 mg every 3 days to achieve a dose of 2500 mg across the three usual meals. If gastrointestinal or other side effects occur, the prior dose without side effects can be used. About half of women treated with metformin will require supplemental insulin.

Prevention of Gestational Diabetes

A prevailing view has been that because T2DM can be prevented by lifestyle interventions and/or insulin sensitizer use, the incidence of GDM should also be able to be reduced. However, only metformin is currently acceptable for use during pregnancy (with the caveats discussed earlier) and has not been shown to be effective for preventing GDM. While outside of pregnancy weight loss is a key factor in preventing progression to T2DM, gestational weight loss is not recommended,[32] and even significant gestational weight gain limitation is not associated with reductions in hyperglycemia development.[74] Indeed, lifestyle interventions have largely been negative, with a Cochrane review yielding a RR of 0.85 (95% CI: 0.71–1.01) of GDM with nutritional and/or exercise interventions, associated with heterogeneity between studies and often insufficient descriptions of interventions.[75] Another metaanalysis of 29 lifestyle RCTs yielded a RR of 0.78 (95% CI: 0.64–0.96) with lifestyle interventions beginning before 15 weeks' gestation but a RR 0.97 (95% CI: 0.82–1.13) in those starting later.[76] Most studies did not exclude women with hyperglycemia at the beginning of pregnancy, among whom GDM is already present, also explaining the heterogeneity that has been shown.

KEY POINTS

- A metaanalysis of 29 lifestyle RCTs yielded a RR of 0.78 (95% CI: 0.64–0.96) with lifestyle interventions, but no significant GDM risk reduction, in studies beginning before 15 weeks' gestation and a RR 0.97 (95% CI: 0.82–1.13) in those starting later.

OBSTETRIC MANAGEMENT OF DIABETES IN PREGNANCY

Obstetric Surveillance

Preexisting Diabetes in Pregnancy. Ideally, the obstetric team should become involved in the management of women with preexisting diabetes before pregnancy, as part of the multidisciplinary preconception planning team. At the first antenatal visit, it is also important to reiterate the rationale for good diabetes management to optimize pregnancy outcomes. Between the obstetrician and the endocrinologist, complications of diabetes (such as nephropathy, cardiac disease, retinopathy) and associated conditions (such as hypertension, thyroid disease, and coeliac disease) should be assessed.

Ultrasound. As for pregnancies in general, a first-trimester ultrasound should be performed to assess the viability of the pregnancy and confirm the gestational age. For women with pregestational diabetes, in the second trimester a fetal anomaly scan should be undertaken at 18 to 20 weeks. Inclusion of a four-chamber cardiac view and the outflow tracts is important because of the increased risk of diabetes-related congenital heart disease.[77]

In the third trimester for both pregestational diabetes and GDM, the focus of the ultrasounds is on fetal growth and well-being. These are commonly performed for growth monitoring, although ultrasound estimation of LGA has not been shown to be more accurate than clinical estimation, and the sensitivity of either for predicting birth weight of 4 kg or more is only 50% to 70%. However sonographic estimation and monitoring of SGA is important, as this is superior to clinical estimation.

Fetal abdominal circumference is a better predictor of birth weight than standard equations for estimating fetal size based on fetal biometry. There is a more rapid increase in fetal abdominal circumference with higher levels of HbA1c. An increase in fetal ultrasound abdominal circumference can also be a useful guide for an insulin treatment strategy in the management of GDM. Asymmetrical growth retardation may be an indication of impaired placental perfusion, and ultrasound monitoring is particularly useful in this situation.

Other Obstetric Screening and Monitoring. Screening for aneuploidy should also proceed as per other pregnancies. First-trimester maternal serum pregnancy-associated plasma protein A levels, and second-trimester alpha fetoprotein and unconjugated estriol levels are decreased in diabetes, so adjustments to the results need to be made. Nuchal translucency scans are unaffected by diabetes.

Maternal assessment of fetal movements is the simplest form of monitoring for fetal well-being. For both pregestational diabetes and GDM, regular fetal monitoring by the nonstress test (cardiotocography) for fetal well-being is usually also recommended from 32 weeks' gestation.[77] A nonreactive nonstress test may indicate fetal compromise. For women with GDM who are medically treated, have poor glycemic control, or have other factors associated with adverse pregnancy outcome, fetal surveillance is also usually recommended. However, the evidence suggests that fetal monitoring is of little benefit for well-managed diet-controlled GDM, and there is no consensus regarding its use among these women.[78] The nonstress test may be combined with an ultrasound to form the biophysical profile, which includes an evaluation of fetal breathing, gross body movements, fetal tone, and amniotic fluid volume. There is a lack of RCT evidence that the biophysical profile improves pregnancy outcomes compared with the nonstress test alone for high-risk pregnancies.

Some units also perform serial uterine artery Doppler studies for women with pregestational diabetes. An abnormal uterine artery systolic to diastolic velocity ratio and the presence of a systolic notch have been shown to have moderate predictive value for preeclampsia and intrauterine growth retardation in high-risk pregnancies.[79]

Timing of Delivery. The timing of delivery is important with the risk of stillbirth weighed up against the risk of neonatal and infant morbidity and mortality. A study of 138,917 women with GDM found that induction of labor or elective cesarean section was associated with a higher risk of neonatal morbidity and mortality compared with expectant management at 36 and 37 weeks, but the risk decreased from 38 weeks.[80] For women with T1DM there was increased risk at 37 weeks, and for T2DM at 36 weeks. One cohort study of 4 million deliveries showed an increase in stillbirth with gestational age beyond 36 weeks, but the nadir for neonatal and infant death was at 39 to 40 weeks.[81] At 39 weeks the stillbirth rate was 5.7/10,000 pregnancies, with a neonatal death rate of 2.6/10,000 and an infant death rate of 8.7/10,000 live births. In general, induction of labor before 40 weeks' gestation has been associated with a lower risk of cesarean section compared with expectant management.[82]

However, in the GINEXMAL RCT, which compared induction of labor at 38 to 39 weeks to expectant management for women with low-risk GDM, no difference was found in the incidence of cesarean section, shoulder dystocia, or admission to neonatal intensive care.[83] In another RCT of women with uncomplicated insulin-requiring gestational or pregestational diabetes, expectant management did not reduce the incidence of cesarean section compared with induction of labor at 38 weeks,[84] but there was an increase in LGA infants and shoulder dystocia.

Most organizations, including the American College of Obstetricians and Gynecologists (ACOG), recommend delivery by 39 to 40 weeks for women with GDM, but not earlier if the pregnancy is uncomplicated.[85] For women with higher-risk GDM or preexisting diabetes, earlier delivery is often necessary to minimize risk to the fetus. The risk of adverse outcomes is affected by factors such as maternal age, maternal weight, estimated fetal weight, and comorbidities or complications, hence these need to be considered in the decision regarding the need for early delivery.

Antenatal Steroids for Preterm delivery

Antenatal steroids, betamethasone or dexamethasone in large doses, are administered to promote fetal lung maturity where premature delivery is threatened or necessary. This may result in women with diet-managed GDM requiring insulin, and women who already are on insulin will require an increase in dosage. Insulin requirements increase by 40% to 45%, peaking at days 2 to 3 after the initial dose of steroid. Even after 5 days, there can be a modest increase in insulin requirement. Local protocols should be in place to enable a rapid response to counter the hyperglycemia arising from antenatal steroids. After 37 weeks' gestation, antenatal steroids are not recommended for women with diabetes because of their association with an increased risk of neonatal intensive care unit attendance with neonatal hypoglycemia (with no excess risk of respiratory issues).[86]

Hypertensive Disorders of Pregnancy

Pregestational diabetes is associated with the development of gestational hypertension and preeclampsia. A recent metaanalysis that included 19 studies with women who had diabetes found that pregestational diabetes was associated with a RR of 3.7 (95% CI: 3.1–4.3) for the development of preeclampsia compared with to the general pregnant population.[87] A systematic review of studies with women who had T1DM determined the prevalence of preeclampsia to be 17%.[88] The presence of diabetic nephropathy, microalbuminuria, retinopathy, and preexisting hypertension were also associated with increased risk.

Some, but not all, studies have shown an association between HbA1c and the development of preeclampsia.

A metaanalysis of studies of prophylactic antiplatelet therapy determined that aspirin therapy reduced the likelihood of preeclampsia by 10%, with this being equally effective among women with diabetes.[89] In a recent RCT with 1776 high-risk women, aspirin 150 mg daily was commenced between 11 and 14 weeks' gestation among intervention subjects.[90] The incidence of preterm preeclampsia was 1.6% in the intervention group and 4.3% in the placebo group, with an OR of 0.38 (95% CI: 0.2–0.74; P = .004). Although neither this study nor any other significant study has specifically focused on women with diabetes, it is widely accepted that the data suggest that low-dose aspirin is just as effective for women with diabetes as for any other high-risk group for the prevention of preeclampsia. The US Preventative Services Task Force and the ACOG recommend low-dose aspirin to optimally be commenced between 12 and 16 weeks' gestation,[77] and the American Diabetes Association recommends that it be commenced by the end of the first trimester for women with pregestational diabetes.[8]

There is an increased risk of gestational hypertension and preeclampsia with GDM, and the risk increases with higher glucose levels, even when below overt diabetes range.[10] There are no studies that have examined the utility of aspirin prophylaxis for preeclampsia in GDM, and there are no recommendations for this. However, in both of the large RCTs of glucose management for GDM, glucose control has been shown to reduce the incidence of preeclampsia.[68,69]

ACE inhibitors and angiotensin 2 receptor blockers are contraindicated in pregnancy, although in some situations they may be used in the first trimester where the benefits outweigh the risks. Antihypertensive agents that are considered safest in pregnancy include labetalol, nifedipine, and methyldopa, although the latter is less favored by the ACOG, as it is less potent.[91] Other agents that have been used are oxyprenolol, hydralazine, prazosin, hydrochlorothiazide, and clonidine.

Decrease in Insulin Requirements

Some pregnant women with T1DM or T2DM experience large reductions in insulin requirement in late pregnancy.[78] This has now been associated with adverse pregnancy outcomes including preeclampsia, preterm delivery, and admission to neonatal intensive care.[78] A decrease in insulin requirements of 15% from the peak dose is also associated with derangement of placental angiogenic factors. A large decrease in insulin requirement is therefore an indicator of potential placental dysfunction and should prompt increased fetal monitoring and a discussion with the obstetrics team.

Peripartum Management and Birth

According to the Pederson hypothesis, maternal hyperglycemia results in fetal hyperinsulinism. At birth, the maternal supply of glucose is terminated, and the fetus becomes dependent on gluconeogenesis and glycogenolysis to meet its glucose requirements. Neonatal hypoglycemia is common, and the incidence is higher if the mother had preexisting diabetes, required insulin, or had higher HbA1c. It is less clear if tight intrapartum glucose control reduces the likelihood of neonatal hypoglycemia, with conflicting findings in the literature.[92] However, it is commonplace for mothers who required larger doses of antepartum insulin to receive an insulin glucose infusion for the delivery to facilitate tight glycemic control.

An insulin glucose infusion is important for women with T1DM to avoid ketoacidosis, although an alternative is for insulin pump therapy to be continued through labor. There is evidence of better glycemic control among women who continue insulin pump therapy through labor and delivery, and having staff who are familiar with their use available minimizes any concerns.[93] Women with T1DM who receive an insulin glucose infusion need to be transitioned back to subcutaneous insulin. Women with GDM can generally have their insulin ceased immediately upon delivery.

An insulin management plan for delivery and postpartum should be developed for each woman who requires insulin during pregnancy. For women who need to continue insulin postpartum (all women with T1DM, and some with T2DM), the requirement is dramatically less than antepartum, with a dose requirement in the order of 50% of the prepregnancy dosage for women with T1DM.[94] Breastfeeding should be promoted, but owing to its increased caloric demands, this may further lower insulin requirements. A proactive reduction in insulin dose is required to avoid hypoglycemia, particularly for women who breastfeed.

LONG-TERM OUTCOMES AND MANAGEMENT OF GESTATIONAL DIABETES

Long-Term Risks of Gestational Diabetes to the Mother

The development of GDM represents an unmasking of an underlying predisposition to diabetes and the metabolic syndrome in general. The majority of women with GDM return to normal glucose tolerance following pregnancy. However, there is a high risk of subsequent diabetes, and this is generally T2DM. The original study by O'Sullivan and Mahan remains the largest study, with the longest duration of follow-up of women with GDM, and a 50% long-term risk of diabetes was observed.[7] A metaanalysis of 20 observational studies found that the risk for T2DM among women who had GDM was almost 10 times that of women who did not have GDM during pregnancy.[95] It has been estimated that up to 31% of parous women who develop T2DM would have had a previous GDM pregnancy.[96]

More recently, the follow-up of 4697 women in the HAPO study has provided data regarding the development of glucose intolerance following GDM as determined by the current IADPSG criteria.[97] After a median follow-up of 11 years, 11% of GDM mothers had developed T2DM, compared with 2% of mothers who did not have GDM (5-fold risk in the adjusted model). For prediabetes it was 42% compared with 18% (3-fold risk in the adjusted model). However, for mothers meeting the more stringent Carpenter–Coustan criteria for the definition of GDM, the incidence of diabetes and prediabetes was considerably higher. As would be expected, this indicates that less stringent criteria for the diagnosis of GDM will define more women as having GDM, but the risk to these women for the development of future diabetes is lower.

There is also evidence that GDM may be a harbinger of T1DM, especially in countries with a higher prevalence of T1DM. In a Finnish 23-year follow-up study, 5.7% of women with GDM developed T1DM, and there were no cases among control women.[98] The onset is usually rapid, with all cases in this study being diagnosed within 7 years of pregnancy.

Women who have had GDM are also more prone to cardiovascular disease. A metaanalysis of nine observational studies found that women with GDM had twice the incident risk of cardiovascular events as women who did not have GDM in pregnancy.[99] Among women who had not yet developed T2D, the increase in risk was 56%. A metaanalysis of 93 studies found that, compared with women without previous GDM, those who had GDM had a 2 mm Hg higher systolic and diastolic blood pressure, were 1.5 kg/m more obese, had 0.3 mmol/L higher total cholesterol, 0.2 mmol/L higher low density lipoprotein cholesterol, 0.6 mmol/L higher triglycerides, and 0.3 mmol/L lower high density lipoprotein cholesterol.[100]

KEY POINTS

- Women with prior gestational diabetes mellitus have a 5- to 10-fold risk of developing type 2 diabetes mellitus over time and double the risk of developing cardiovascular disease.

Benefits of Breastfeeding for the Mother

It is strongly recommended that women who have had GDM or preexisting diabetes in pregnancy breastfeed their newborns. In addition to the health benefits of breastfeeding for the child, there is evidence that breastfeeding may have positive effects for maternal metabolism as well. Breastfeeding increases maternal energy expenditure by 15% to 25% per 24 hours. This is associated with lower maternal glucose, insulin, and lipid levels, as well as better weight control. In addition, it improves insulin sensitivity.

In the SWIFT Study, Latina women who had GDM were prospectively followed for 2 years with annual OGTTs.[101] There were graded associations between lactation intensity and duration with the development of T2DM. Women who exclusively breastfed or breastfed for more than 10 months had half the incidence of diabetes compared with women who exclusively formula-fed,[101]

Postpartum Follow-up of Mothers

Because GDM may reflect underlying preexisting diabetes, it is routinely recommended that women with GDM be tested by a 75-g OGTT in the first 3 months postpartum.[15] An OGTT is preferred over an HbA1c test for diabetes screening, as the HbA1c may be affected by red cell changes during pregnancy or blood loss at delivery.

The increased risk of T2DM and cardiovascular disease following a GDM pregnancy highlights the need for ongoing follow-up, screening, and cardiovascular risk factor management. Ongoing diabetes screening every 1 to 3 years is recommended, by HbA1c, fasting glucose, or 75-g OGTT.[8].The OGTT is more sensitive in the short-term detection of diabetes in this cohort of women, as GDM diagnosed by an increased glucose level in response to a glucose load is more likely to be associated with diabetes diagnosed in response to a glucose load.[102] However, because it is less convenient, this may be a barrier to testing.

When caring for women who have had GDM, particular attention should be paid to the long-term management of cardiovascular risk factors. This includes healthy eating, undertaking regular physical activity, healthy weight management, and lipid and blood pressure screening and management. In prospective observational studies, women who follow healthier eating patterns have a reduced risk of developing T2DM. Both intensive dietary and physical interventions, as well as metformin, as demonstrated by the Diabetes Prevention Program, reduce the progression from impaired glucose tolerance to T2DM among women with GDM . In the GEM Study, conducted among women who had recent GDM, also with lifestyle coaches and dietitians supporting a target of achieving the pregravid BMI if this was less than 25 kg/m^2 or losing 5% of body weight if the pregravid BMI was greater than or equal to 25 kg/m^2 and engaging in 150 minutes of moderate to intensive physical activity per week was effective in increasing physical activity and the achievement of weight goals after 6 months.[103] However, this study was unable to demonstrate a reduction of diabetes within this short time frame.

Postpartum Follow-Up of Offspring

Long-Term Risks of Gestational Diabetes and Preexisting Diabetes in Pregnancy to the Offspring

Risk of Diabetes and Glucose Intolerance to the Offspring. The concept that hyperglycemia *in utero* results in fetal programming that predisposes the offspring to future obesity and diabetes began with the landmark studies of Pettit et al., who followed the offspring of Pima Indian women who had an OGTT during pregnancy. The worse the maternal glucose status during pregnancy, from normal to impaired glucose tolerance to diabetes, the greater was the likelihood of the offspring developing diabetes by the age of 24 years.[104] A dose-response relationship was also demonstrated between the maternal 2-hour glucose levels on the OGTT in pregnancy, with the prevalence of the offspring having impaired glucose tolerance or diabetes during their own pregnancy. In further sibship studies, it was demonstrated that this was not caused by genetic predisposition, and is therefore more likely to be directly related to the level of maternal glycemia in pregnancy.

More recently, there are data from the HAPO study demonstrating a similar relationship for the offspring of women with untreated hyperglycemia in the GDM range.[105] At age 10 to 14 years, 4160 children from the original cohort were evaluated with an OGTT. There was a positive association between maternal glucose levels on the OGTT during pregnancy and child glucose levels and HbA1c.[106] The prevalence of impaired glucose tolerance among the offspring of mothers who met criteria for GDM (but who were not treated) was 11% compared with 5% for mothers who did not have GDM. For impaired fasting glucose by American Diabetes Association criteria, the prevalence was 9% compared with 7%, respectively.[105] There was an inverse association between maternal glucose levels and child insulin sensitivity and disposition index, as determined by the Matsuda index.[107]

Risk of Obesity to the Offspring

Older studies have demonstrated that the severity of maternal glucose intolerance in pregnancy is not just associated with offspring glucose intolerance, but also with obesity in the offspring. In the follow-up of offspring in the HAPO study, 40% were overweight or obese if the mother met criteria for GDM, compared with 29% where the mother did not have GDM.[97] However, in a fully adjusted model (including maternal weight), the difference was not significant. These findings highlight the difficulty of teasing out the effect of intrauterine glucose exposure from the effects of genetics and family environment. Although multiple studies have now demonstrated a relationship between maternal HIP and offspring glucose intolerance and obesity, there remains as yet no good evidence that treatment of maternal glycemia alters this risk.

Risk of Neurocognitive Disorders and Autism in the Offspring

The suggestion that there is a link between hyperglycemia in pregnancy and neurocognitive disorders arose from correlations between measures of neurobehavioral development and HbA1c during pregnancy. A recent metaanalysis found that offspring exposed to maternal preexisting diabetes scored a mean of 3 intelligence quotient points lower than normal control subjects.[108]

An association between maternal preexisting T2DM and early GDM with the development of autism spectrum disorder in the offspring has been observed, although the relationship with maternal T2DM lost significance after adjustment.[109] At this point, the data regarding neurocognition and autism need to be viewed with caution, given the difficulty in controlling for potential confounders and the lack of prospective data.

Potential Mechanisms for Long-term Effects of Preexisting Maternal Diabetes and Gestational Diabetes on the Offspring

Freinkel modified the Pederson hypothesis to arrive at the concept of "fuel-mediated teratogenesis."[1] He postulated that the excessive transplacental passage of glucose, amino acids, and lipids in diabetic pregnancy leads to fetal programming changes that may affect adult health. There is now some evidence that epigenetic changes contribute to the fetal programming effect.

Epigenetic changes are heritable molecular mechanisms that alter gene expression without changing DNA sequences. These can result from environmental factors, and the preconception period, fertilization, gestation, and early years of life are periods of higher susceptibility. DNA methylation, histone modifications, and noncoding RNAs are potential epigenetic mechanisms. Epigenetic changes, including those that develop *in utero*, can be passed to the next generation, resulting in a transgenerational effect.

In human studies, differential DNA methylation has been demonstrated between cord blood from GDM pregnancies and controls.[110] In particular, there are differentially methylated regions associated with diabetes, metabolic disease pathways, obesity, insulin secretion, and coronary artery disease. Differential DNA methylation in genes associated with schizophrenia and schizoaffective disorders has also been found in placental samples. In an epigenome-wide association study that examined cord blood, GDM was associated with lower methylation of genes associated with autism spectrum disorder and T1DM and T2DM.[111] The study of epigenetics is likely to reveal much more about the fetal programming effects of the intrauterine environment in years to come.

SUMMARY AND FUTURE DIRECTIONS

The management of HIP should commence before conception, whether through prepregnancy planning or pregnancy avoidance (preferably using LARC), among those with known preexisting diabetes, or through weight management and diabetes prevention among women at risk of diabetes. Antenatal management is complicated and challenging for many women and requires ongoing supervision and early counseling regarding the risks and need for frequent visits to review and, where necessary, adjust medication. Postpartum management means a major downward reduction in medications and promotion of breastfeeding and maintenance of weight management and physical activity. Women and their partners need to be aware of the potential long-term risks for the offspring and the need to adopt a family approach to reducing this risk through healthy lifestyles.

HIP is experiencing rapid change and future directions, including:

- Ongoing development of technology and testing, whether or not these benefit the mother and offspring. The required tight glycemic targets are not yet possible for many women.
- Identifying the optimal glycemic targets during each trimester of pregnancy requires the performance of trials that include the use of TIR alongside pre- and postprandial targets.
- Obtaining evidence for the optimal criteria for the diagnosis of GDM in the first trimester and before 20 weeks' gestation and whether treatment is beneficial or harmful.
- Obtaining evidence for the optimal criteria for the diagnosis of GDM at 24 to 28 weeks; these may change with dividing GDM into that present early in pregnancy (i.e., already present or prevalent GDM) and that which develops *de novo,* usually by 24 to 28 weeks' gestation (i.e., incident GDM).
- Further research into models of care to normalize as many pregnancies as possible, to ensure that pregnancy is as positive an experience for women with diabetes as for women without diabetes.
- Further research into the heterogeneity of GDM and the potential for personalized care (including cost-effective approaches to detecting monogenic diabetes).
- Further research into preventing GDM before pregnancy or in the first trimester and into optimizing lifestyle choices during pregnancy among women with diabetes.
- Further research into ways to prevent progression to T2DM and cardiovascular disease among women with prior GDM, including strategies for widespread implementation.
- Further research into the long-term harm to the offspring of exposure to antenatal excess fuel supply, as well as the long-term benefits and possible harms from treatment of HIP.

Atypical Antipsychotic Agents, 626

Conclusion, 627

Plasma glucose levels in humans are normally maintained between 70 and 180 mg/dL. Plasma glucose levels outside of this range lead to acute and chronic complications. Central nervous system function is exquisitely sensitive to blood glucose levels. Acute hypoglycemia impairs cognitive function and, if severe (<30 mg/dL) and prolonged (>6 hours), may lead to irreversible brain damage. Severe acute hyperglycemia causes hyperosmolar coma, which can cause irreparable brain damage. Chronic hyperglycemia above 180 to 200 mg/dL impairs physiologic processes such as protein synthesis and phagocytic function and can result in both microvascular and macrovascular diseases. Because maintaining normal glucose homeostasis is essential, many physiologic processes regulate plasma glucose levels. Insulin and glucagon secretion are the major regulators, whereas catecholamine and gastrointestinal incretin hormone secretions modify regulation in specific circumstances.

Insulin promotes hepatic glucose uptake and glycogenesis, stimulates muscle and adipose tissue glucose uptake and metabolism, and inhibits adipose tissue lipolysis and muscle proteolysis. Glucagon stimulates hepatic gluconeogenic precursor uptake and increases hepatic glycogenolysis, gluconeogenesis, and ketogenesis. Because insulin and glucagon have opposite effects, the ratio of the two hormones mitigates normal plasma glucose levels. A fall in plasma glucose suppresses insulin secretion and stimulates glucagon secretion. A rise in plasma glucose stimulates insulin secretion and suppresses glucagon secretion.

Insulin effects on cells are mediated by a series of intracellular events that occur following insulin binding to plasma membrane insulin receptors. These intracellular events that mediate insulin's actions may be modified by other intracellular events and thus can make the effect of a plasma insulin concentration greater or less. An increase in fatty acid products within a muscle or adipose tissue cell diminishes insulin's effects in increasing glucose transport into the cell. The cell's ability to respond to insulin is referred to as insulin sensitivity. Because insulin secretion is determined by the plasma glucose level, a decrease in insulin sensitivity normally causes a compensatory increase in insulin secretion, which restores plasma glucose homeostasis. Hyperglycemia occurs when either there is an absolute deficiency in insulin secretion or when β cell insulin secretion cannot increase sufficiently to overcome a decrease in insulin sensitivity (insulin resistance).

Except for maturity onset of diabetes in youths, most types of diabetes mellitus (DM) are heterogeneous disorders in which gene polymorphisms provide the predispositions, and environmental factors serve as the precipitating causes of hyperglycemia. These gene polymorphisms are multiple and can affect β cell function or insulin sensitivity. Many individuals with some genetic predispositions to develop hyperglycemia may not manifest impaired glucose tolerance (IGT) or fasting hyperglycemia throughout their lifetime unless they are exposed to some environmental factor that exaggerates the effects of these polymorphisms. If a pathologic condition develops in such individuals, or if they take a medication that disturbs their compensated state, hyperglycemia will develop. Thus, hyperglycemic states resulting from nondiabetic conditions or therapies can be subdivided into those that can cause hyperglycemia in any individual because they radically interfere with a major regulatory pathway (Table 35.1) and those that precipitate diabetes only in genetically predisposed individuals because they alter the compensated state (Table 35.2). Because of the high prevalence of a genetic predisposition to type 2 diabetes in various populations, it is not always possible to make the distinction with certainty.

KEY POINTS

- Primary regulators of glucose homeostasis are insulin and glucagon secretion. Hyperglycemia occurs when a pathologic process or drug causes a primary defect in pancreatic β cell insulin secretion or when the β cell cannot compensate with enough insulin secretion to overcome an induced insulin resistance.

HYPERGLYCEMIA AND DISORDERS OF THE PANCREAS

Hyperglycemia and DM caused by disorders of the pancreas are classified as type 3c diabetes. An analysis of 1868 patients with DM evaluated during a 2-year period at University Hospital in Giessen, Germany determined that 23% had type 1, 67% had type 2, and 9.2% had type 3c diabetes.[1] The specific diagnoses of the 172 patients classified as type 3c diabetes were: chronic pancreatitis (CP), 79%; pancreatic cancer 8%; post–pancreatic resection 2%; cystic fibrosis (CF) 4%; and hereditary hemochromatosis 7%.

The characteristics of the hyperglycemia of the various disorders of the pancreas will depend on whether the pathologic process is uniform through the pancreas or whether it is restricted to a lobe of the pancreas as in pancreatic cancer or surgical pancreatectomy.

TABLE 35.1 Conditions That Can Cause Hyperglycemia in the Absence of Known β Cell Genetic Abnormalities

- Diseases of the Pancreas
  - Pancreatectomy
  - Trauma
  - Acute pancreatitis
  - Chronic pancreatitis
  - Autoimmune pancreatitis
  - Fibrocalcific pancreatitis
  - Pancreatic carcinoma
  - Hemochromatosis
  - Hemosiderosis
  - Amyloidosis
  - Cystic fibrosis
- Overproduction of Other Islet Hormones
  - Glucagonoma
  - Somatostatinoma
- Drugs and Toxins
  - Pyriminil (Vacor)
  - Pentamidine
  - Interferon α
  - K_{ATP} channel openers
  - Phenytoin (Dilantin)
  - Immune checkpoint inhibitors
  - mTOR and phosphoinositide 3-Kinase inhibitors
  - L-Asparaginase

Pancreatectomy

The pancreas is formed by fusion of the ventral and dorsal pancreatic protrusions from primitive gut endoderm.[2] The islets of the anterior head of the pancreas and the tail arise from the ventral pancreatic protrusion and contain 80% β (insulin-producing) and 15% α (glucagon-producing) cells. The islets of the posterior protrusion (uncinate lobe) contains 80% γ (pancreatic polypeptide–producing) cells. The tail of the pancreas contains twice the islet cell mass as the head or body. Human pancreatic islets contain 30% α cells, 60% β cells, and 10% δ (somatostatin-producing) and γ cells.

DM occurring after surgical removal of the pancreas is insulin-dependent. It is characterized by insulin and glucagon deficiency.[3] The magnitude and characteristics of the hyperglycemia depend on the quantity of pancreas removed (Table 35.3). Total or near-total pancreatectomy results in severe hyperglycemia, decreased plasma insulin, virtually absent plasma glucagon, and elevated plasma levels of

TABLE 35.2 Conditions That Precipitate Hyperglycemia in Individuals With a Genetic Predisposition to Type 2 Diabetes

- Endocrinopathies
  - Acromegaly
  - Cushing syndrome
  - Pheochromocytoma
  - Hyperthyroidism
- Drugs
  - Drugs that interfere with insulin secretion
    - β-adrenergic antagonists
    - Diuretics
  - Drugs that impair insulin action
    - Glucocorticoids
    - Oral Contraceptives
    - Nicotinic Acid
    - Statins

TABLE 35.3 Estimated Frequency of Diabetes Reported in Pancreatic Diseases

95% pancreatectomy	100%
50% pancreatectomy	0% in 2-year follow-up 26% in 9.6- to 16-year follow-up
Pancreatitis	
Acute after 1 year	15%
Acute long-term	30%–40%
Chronic calcifying	
(increases with duration of disease)	40%–70%
Chronic noncalcifying	15%–30%
Cystic fibrosis	
Childhood	2%
Adolescence	20%
Adult	40%–50%
Pancreatic carcinoma	
At diagnosis	68%
Diabetes mellitus onset ≤2 years from diagnosis	55%
Hemochromatosis	
Diagnosed by clinical criteria	35.6%
Diagnosed by genetic testing	17.7%

gluconeogenic precursors (alanine, lactate, glycerol). When exocrine function is significantly reduced, the ensuing malabsorption results in diminished meal-mediated incretin release, which contributes further to the diminished insulin secretion.[4]

The effect of a 50% pancreatectomy was evaluated in 28 normal transplant donors 1 year after surgery.[5] The donors lost a mean of 3.4 kg of body weight, and their mean fasting plasma glucose (FPG) level had risen by 9 mg/dL (88 ± 7 to 97 ± 16 mg/dL). Similarly, their mean serum glucose concentration 2 hours after an oral glucose load was higher (117 ± 18 to 156 ± 53 mg/dL), and the area under the 5-hour plasma glucose curve after oral glucose was 19.5% higher. Both the mean fasting plasma insulin concentration and the area under the 5-hour plasma insulin curve were significantly lower than preoperatively (–14% and –31%, respectively). None of the donors had any evidence of deficient pancreatic exocrine function. Further analysis noted that 21 of the donors had no significant postoperative change in plasma glucose or insulin, whereas seven showed a marked increase in the entire 5-hour plasma glucose curve (either IGT or DM) with no concomitant increase in 5-hour plasma insulin curves. The seven donors in whom some degree of hypoinsulinemia and hyperglycemia had developed did not have fasting hyperglycemia 1 year postoperatively. Two of the seven were studied from 2 to 7 years after surgery and had not had a further increase in FPG. Evaluation of eight donor/recipient pairs evaluated 9 to 18 years after their original surgery indicated that residual pancreatic mass is a significant determinant of long-term glucose homeostasis.[6] However, other variables were implicated in the discordancy for the development of DM. Obesity seemed to be a major factor, in that all individuals (four donors and two recipients) who had developed DM were among the eight patients who were obese. The data were interpreted as “suggesting that obesity should be a contraindication to donation of pancreatic segments and that donors should assiduously avoid becoming obese.”

In a 3- to 10-year follow-up of 21 normal individuals who had donated 50% of their pancreas between 1997 and 2003, two donors were taking oral diabetic medications, two had impaired FPG (IFG), one had IGT, three had both IFG and IGT, and one met the criteria for the diagnosis of diabetes.[7] Six of the patients were lost to follow-up. Only six of 15 patients with follow-up data had normal glucose values. Despite the use of stringent criteria to exclude those at risk for developing abnormalities in glucose metabolism, 43% of the total population of healthy individuals who underwent a 50% pancreatectomy developed some abnormality of glucose metabolism.

Follow-up of 46 living donors who underwent segmental pancreas donation from 1994 through 2013 found that seven had developed DM requiring oral hypoglycemic agents after a mean of 9.2 ± 3 years, and five had developed insulin-dependent diabetes after a mean of 7 ± 5.4 years.[8] Risk factors for developing DM were initial FPG of 100 mg/dL or more, 2-hour plasma glucose during an oral glucose tolerance of 120 mg/dL or more, basal insulin of 9 μU/mL or more and an increase in body mass index (BMI) after surgery greater than 15%. Data from a USA Scientific Registry of Transplant Recipients (1987–2015) were matched with records from a nationwide pharmacy claims warehouse (2005–2015) for diabetes medications and supplies as a measure of postdonation DM.[9] Among 73 pancreas donors, 45 were identified in the pharmacy database. Over a mean follow-up of 16.3 years, 26.7% fulfilled the criteria for DM, compared with 5.9% of matched kidney donors. The prevalence of insulin use was 11.1% in pancreas donors versus 0% in kidney donors, and the prevalence of oral antidiabetic use 20.0% versus 5.9%.

Studies in patients with a 50% partial pancreatectomy because of CP ($n = 14$), pancreatic carcinoma ($n = 10$), or extrapancreatic tumors impinging on the pancreas ($n = 13$) showed improvement in glucose tolerance compared with the baseline abnormalities several weeks following surgery.[10] This was greatest in those with CP. Resection of the head of the pancreas improved glucose tolerance, whereas resection of the tail of the pancreas caused worsening of glucose tolerance. Insulin and C-peptide secretion were decreased equally by both surgical procedures. Repeat studies 3 years after surgery in both the CP and extrapancreatic tumor patients showed restoration of glucose tolerance to initial baseline values.[11] Postchallenge insulin and C-peptide concentrations that had reduced after surgery were partly normalized at the time of follow-up. These data suggest that some regeneration can occur in the adult pancreatic islets. Sun and colleagues studied the metabolic effects of removing 20% to 88% of the pancreas in dogs and found that no significant metabolic changes occurred until approximately 50% had been removed.[12] From the available data, it appears that metabolic abnormalities are clinically relevant after removal of 50% of the pancreas and increase progressively as the extent of pancreatectomy increases. The concomitant presence of insulin resistance further increases the likelihood of metabolic abnormalities.

Characteristics of DM following total or extensive pancreatectomy include an absence of glucagon secretion and marked impairment in insulin secretion. Absence of glucagon slows, but does not interfere with, the development of hyperglycemia and ketonemia after insulin withdrawal. Although not necessary for development of the metabolic abnormalities of insulin- dependent DM, the presence of glucagon increases the metabolic abnormalities of insulin deficiency, and the absence of glucagon secretion does leave a pancreatectomized individual with diabetes at high risk for severe hypoglycemia during insulin treatment.[13,14] This situation is exaggerated by the associated nutritional deficiencies and weight loss that ordinarily accompany exocrine pancreatic insufficiency. A concomitant deficiency of pancreatic polypeptide may contribute to persistent hyperglycemia caused by impaired hepatic insulin action.[15] Treatment of an individual with pancreatectomy-induced diabetes requires insulin, is associated with marked lability in glucose regulation, and is linked with an increased rate of both ketoacidosis and death from hypoglycemia. The development of autonomic neuropathy in such a patient greatly adds to the risk for severe hypoglycemia with insulin treatment.

Patients with total pancreatectomy can maintain reasonably good glycemic control with few serious hypoglycemic or ketoacidosis events provided they use self–blood glucose monitoring or continuous glucose monitoring (CGM) and are followed closely by their physicians.[16] Among 33 patients available for a median follow-up of 50 months, the median hemoglobin A1c (HbA1c) level was 8.2%, which was comparable to that in type 1 diabetic patients followed at the same institution. Patients resected for cancer maintained better glycemic control than those treated for CP. The median insulin dose for the entire group was 46 units per day.

A feasible method for minimizing the development or severity of DM following major or total resection of the pancreas is isolation and autotransplantation of the individual’s islets. Among 20 of 37 nondiabetic patients who had undergone islet autotransplantation after a 50% to 60% distal partial pancreatectomy for benign pancreatic tumors, the 7-year diabetes-free survival rate was 51%.[17] The response was a function of the islet yield per gram of pancreas weight and was greatest when there were more than 5154 islet equivalents per gram (IEQ/g). The proportion of patients with IGT 2 years after distal pancreatectomy was 12/16 in the control group, 6/7 in patients with less than 5154 IEQ/g and 3/11 in those with greater than 5154 IEQ/g.

KEY POINTS

- Resection of 50% of the pancreas will result in a progressive deterioration of glucose metabolism that is minimal after 2 years but results in frank diabetes mellitus in approximately 26% of pancreatic donors after 10 to 16 years. Those who are most likely to develop glucose intolerance are those who gain excessive weight and those with the initial FPG greater than 100 mg/dL. Resection of the head of the pancreas is associated with preserved or improved glucose metabolism, whereas resection of the tail of the pancreas results in deterioration of glucose metabolism. Total pancreatectomy is characterized by severe insulin, glucagon, and exocrine pancreatic deficiency. Patients with total pancreatectomy are insulin-dependent, require pancreatic enzymes, and are at risk for hypoglycemia or ketoacidosis. Autologous pancreatic islet transplantation is a good therapeutic option if possible.

Acute Pancreatitis

Acute pancreatitis (AP) is an inflammatory disease of the pancreas and is the leading cause of hospitalization for gastrointestinal disorders in the United States. Risk factors for AP include gallstones, blockage or manipulation of the pancreatic ducts, or alcohol misuse. Hyperglycemia is a common early feature of AP and was generally considered to be a transient phenomenon that completely resolved in almost all patients.[18,19] However, a metaanalysis of 24 prospective clinical studies involving 1102 patients with a first episode of AP, published in 2014, showed that prediabetes and/or DM occurred in 37% of individuals after AP.[20] The pooled prevalences of prediabetes, DM, and insulin-treated DM after AP were 16%, 23%, and 15%, respectively. Newly diagnosed DM developed in 15% of individuals within 12 months after the first episode of AP, and the risk increased to nearly 40% by 5 years (relative risk 2.7). A similar trend was observed with insulin treatment. The severity of AP, its etiology, age, and gender had minimal effect on the glycemic outcomes.

Subsequently, individual centers have reported mean follow-ups of 2.7 and 3.5 years in 113 and 100 patients with AP and found the prevalence of new-onset DM to be 14% and 30% and the prevalence of exocrine pancreatic insufficiency to be 21% and 29%, respectively.[21,22] A metaanalysis of 234 patients with AP followed for 12 to 179 months reported a prevalence of prediabetes and new-onset DM of 43% and prevalence of pancreatic exocrine insufficiency of 29%. Pancreatic exocrine insufficiency occurred in 40% of those who developed prediabetes or DM.[23]

A retrospective analyses of case records from 2.36 million patients from primary care practices in England reported in 2017 that diabetes occurring after a median follow-up of 4.5 years from the onset of pancreatic disease was 2.59/100,000 person-years.[24] This was greater than the onset of new type 1 diabetes. Diabetes following AP was more common than that following CP (361 vs. 91 patients). The majority of the 559 cases of pancreatic diabetes had been diagnosed as type 2 diabetes (87.8%). Patients with pancreatic diabetes at diagnosis had a median age of 59 years and a median BMI of 29.2 kg/m^2. Patients with pancreatic diabetes had poorer glycemic control than type 2 diabetic patients, and insulin use within 5 years was 20.9% in diabetes following AP and 45.8% in patients with CP, as compared with 4.1% in patients with type 2 diabetes. A population-based study of 3 million residents of New Zealand over a 10-year period reported a prevalence of diabetes associated with exocrine pancreas disease to be 1.13/1000 individuals, with AP contributing 61% to the overall prevalence.[25]

The high prevalence of insulin-dependent DM following a single bout of AP, regardless of severity, suggests that a significant percentage may be autoimmune in origin. Several studies have reported the presence of glutamic acid decarboxylase or other antiislet antibodies in some patients with AP. An increase in serum GIP and peptide YY that correlated with increases in interleukin-6, tumor necrosis factor α, and monocyte chemoattractant peptide was reported in 83 individuals following an episode of AP.[26] A hypothesis to be tested is that destruction of exocrine pancreatic tissue stimulates an intensive inflammatory response that triggers an islet cell immune response in genetically susceptible individuals.

Chronic Pancreatitis

CP is characterized by fibrosis and inflammation of the pancreas. In the United States the prevalence of CP is between 42 and 73/100,000 adults.[27] Specific pathologic and clinical findings are pancreatic atrophy, fibrosis, ductal strictures and distortion, calcifications, exocrine and endocrine deficiency, and chronic pain.[27-31] Excessive alcohol consumption is the most common etiology for CP (relative risk in US and European populations 2.7–3.3).[27,28] Idiopathic CP is the second most common etiology, accounting for 28% to 80% of cases, depending on the population assessed.[27,31] A number of susceptibility genes for CP have been recognized. These include variants of genes involved in trypsinogen activation (cationic trypsinogen 1, anionic trypsinogen, serine protease inhibitor Kazal type 1, and chymotrypsin C) and genes involved in intrapancreatic trypsin regulation (cystic fibrosis transmembrane conductance regulator [*CFTR*] and calcium-sensing receptor).[31] These genes not only are associated with idiopathic CP but also increase the susceptibility to other risk factors for CP. These genetic variants occur in 47.8% of idiopathic CP patients in a US population and 57.1% in a Chinese population (compared with 5.9% of control patients).[31] Smoking is associated with CP in a dose-dependent manner.[10,11] Hypertriglyceridemia, hypercalcemia, and autoimmune disease are less common risk factors for CP.[27-30] The underlying pathologic process in CP is destruction of acinar cells with release of activated enzymes, leading to necrosis and inflammation.

CP has been thought to account for less than 1% of DM in Western countries and Japan. Several recent publications dispute this and have reported a prevalence of 7.2% to 8%.[29,32] The presumed reasons for failure to recognize the higher prevalence of pancreatic diabetes (type 3c diabetes) have been misdiagnosis and lack of clear diagnostic criteria. In tropical countries, fibrocalculous pancreatic diabetes occurs with a self-reported prevalence of 0.36%.[33] The incidence may be somewhat higher, but comprehensive data are not available. Diabetes resulting from CP can be differentiated from type 1 and type 2 diabetes by an absent pancreatic polypeptide response to a mixed meal, insulin-induced hypoglycemia, or secretin infusion.[34] The development of DM in patients with CP is most frequent in those with calcific disease (55%–70%) and occurs less often in those with noncalcific disease (30%).[35] The prevalence of diabetes in patients with CP increases with increasing duration of pancreatitis and with increasing exocrine deficiency.

The inflammatory response causes loss of exocrine tissue, extensive fibrosis, and distorted and blocked ducts. The islets of Langerhans are relatively resistant and undergo pathologic changes only late in the disease. CP is associated with decrease in pancreatic mass, a loss of functioning β cells of approximately 29%, and a lesser loss of α cells.[36,37] Hormonal alterations include a decrease in insulin secretion in response to nutrients, followed later by a decrease in fasting C-peptide levels. Plasma C-peptide levels rather than insulin levels are a better means of assessment of insulin secretion in CP, because associated liver disease may change hepatic extraction rates of insulin. With progressive CP, insulin secretion falls even lower. Glucagon secretion is impaired in moderate to severe CP.[37-39] Insulin resistance frequently develops in such individuals.

DM is seen after several years of CP. In an unselected series of patients with CP, 35% of cases resembled type 1 diabetes, 31% resembled type 2 diabetes or IGT, and 34% exhibited normal glucose tolerance.[39] In a series of 2011 patients with CP followed for a mean of 22 years, the duration of the CP determined the prevalence of DM: the cumulative rate at 29 years was 45.8%, and at 50 years was 90%.[40] Mild pancreatitis may be associated only with IGT, whereas severe pancreatitis is associated with insulin dependency. Patients with CP and DM fail to secrete glucagon in response to hypoglycemia. Incretin secretion is frequently impaired. If patients have concomitant autonomic neuropathy, they are extremely susceptible to severe and prolonged hypoglycemia.

Pancreatic exocrine function has been reported to be reduced in some type 1 and type 2 diabetic patients. Although this has been explained as a complication of diabetes, the relationship between exocrine and endocrine function of the pancreas makes it difficult to distinguish patients with DM who have developed secondary exocrine deficiency from patients with primary pancreatic exocrine disease who have developed islet cell deficiency, and secondarily DM. A retrospective analysis of pancreatograms of patients with known diabetes has suggested that CP may be much more common as a cause of diabetes than was previously thought.[41] A total of 38 type 1 and 118 type 2 diabetic patients underwent endoscopic retrograde cholangiopancreatography studies for various reasons. Pancreatic ducts were classified as normal in 23.3% and as exhibiting CP degree I, II, and III in 22.7%, 32.7%, and 21.3%, respectively. The investigators suggested that a substantial number of patients with primary DM may have a concomitant CP, or perhaps many cases of primary DM may be related to CP.

Treatment of DM in patients with CP should entail the use of small doses of short-acting or rapid-acting insulins to manage the hyperglycemia, replacement enzymes for the malnutrition and malabsorption, and elimination of the use of alcoholic beverages.[27,29,31,38,39] Surgery with subtotal resection or near-total resection may be necessary to relieve severe pain. Following pancreatic surgery for pain or other complications, there is a significant incidence of DM; however, whether diabetes develops is dependent on the type of surgical intervention used. Whipple procedures usually are associated with an incidence of 25% to 40%, a Frey or Berne procedure 8% to 22%, and a distal pancreatectomy approximately 60%.[42,43] In such patients, successful islet allotransplants and autotransplants in the liver have been able to maintain near-normoglycemia. The hepatic islet cell transplants secrete insulin in response to nutrients but are unable to secrete glucagon in response to hypoglycemia. A recent report of the results of pancreas allotransplants in patients who had undergone total pancreatectomy in the past showed a 70% survival rate and successful correction of both exocrine and endocrine deficiencies.[44]

Sutherland and coworkers have summarized their experience with 409 patients with CP and severe, unrelenting pain who underwent a total pancreatectomy with islet autotransplantation.[45] The etiology of the CP in most of the patients was idiopathic, familial, or pancreas divisum. The 5-year survival rate was 90%. The status of glucose control following the surgery was directly proportional to the IEQ/kg transplanted.[45] The patients were classified as receiving less than 2500 IEQ/kg, 2500 to 5000 IEQ/kg, or greater than 5000 IEQ/kg. Glucose control status was defined as insulin-independent, partial function, or insulin-dependent. At 3 years after surgery, 72% of patients who received greater than 5000 IEQ/kg were insulin-independent, whereas 24% had partial function, and 4% were insulin-dependent. In contrast, 12% of those receiving less than 2500 IEQ/kg were insulin-independent, 33% had partial function, and 55% were insulin-dependent. Some 22% of those receiving 2500 to 5000 IEQ/kg had insulin independence, whereas16% had insulin dependence. The percentage of patients with mean HbA1c less than 7% at 3 years was 71% for those who received less than 2500 IEQ/kg 86% for those who received 2500 to 5000 IEQ/kg, and 94% for those who received greater than 5000 IEQ/kg.

KEY POINTS

- Acute pancreatitis is the commonest gastrointestinal disorder requiring hospitalization. Etiology is most often caused by gallstones, obstruction of the pancreatic duct, or excess alcohol ingestion. Acute pancreatitis leads to diabetes mellitus (DM) in 40% of patients within 5 years. A significant proportion of the diabetes is insulin-requiring and is thought to represent the result of autoimmune activation secondary to pancreatic inflammation. Chronic pancreatitis is a recurring inflammatory disease of the exocrine pancreas that causes progressively more severe abdominal pain and exocrine deficiency, followed by islet destruction, and secondarily DM. The commonest etiologies are chronic alcohol use or idiopathic. Variants of several genes regulating pancreatic exocrine secretions have been associated with the development of chronic pancreatitis. The prevalence of DM increases with duration of chronic pancreatitis and is close to 70% after 20 years. DM owing to pancreatitis is often confused with type 2 diabetes and may account for as much as 5% to 8% of total DM cases. Severe recurrent abdominal pain in patients with chronic pancreatitis may require total pancreatectomy, in which case autologous islet transplantation is recommended to control glucose metabolism.

Pancreatic Cancer

Pancreatic ductal adenocarcinoma is the fourth leading cause of cancer deaths in the United States. Because most patients have extensive disease spread at the time of diagnosis, the reported 5-year survival ranges from 1% to 8%.[46,47] DM is greatly increased in patients with invasive ductal pancreatic cancer. The relationship between DM and pancreatic cancer is bidirectional, in that longstanding DM is associated with an increased risk for the development of pancreatic cancer, and pancreatic cancer is associated with an increased risk for the development of new-onset DM (occurring ≤2–3 years before the diagnosis of pancreatic cancer).[48-51] In a comparative study, DM occurred in 68% of patients with pancreatic cancer compared with 19.8% of age-matched patients with lung cancer, 19.4% with breast cancer, 14.8% with prostate cancer, 20.7% with colon cancer, and 23.5% of noncancer controls.[52] Longstanding DM has a relative risk for the development of pancreatic cancer of approximately 1.6 compared with nondiabetic individuals, which is similar to the risk for several other cancers. This risk is increased by poor glycemic control. Pancreatic cancer is associated with a 5- to 8-fold increased risk for newly diagnosed DM. This increased risk can be identified by increasing FPG, worsening oral glucose tolerance, or the diagnosis of DM starting at 36 months and becoming progressively higher up to the time that pancreatic cancer is diagnosed.[53] These data suggest that pancreatic cancer itself is the cause of the new-onset DM. The observations that longstanding DM is unchanged or slightly worse after surgical removal of the tumor, whereas new-onset diabetes is markedly diminished after tumor resection, provide substantial proof for this hypothesis. Arising fasting plasma glucose (FPG) level, a deteriorating oral glucose tolerance test (OGTT), or the development of DM in a previously normal glucose-tolerant individual can be an early indication of pancreatic cancer. An additional factor that heightens the suspicion for pancreatic carcinoma is the progressive weight loss accompanying new-onset deterioration of glucose control. The development of ordinary type 2 diabetes is generally accompanied by weight gain, with weight loss ensuing only after the development of severe hyperglycemia. In a study from the Mayo Clinic, it was observed that the increase in FPG at the time of diagnosis, as well as up to 24 months before diagnosis of pancreatic cancer, was positively correlated with the volume of the resected tumor from greater than 1.0 mL to greater than 16.0 mL.[3] Wakasugi and colleagues reported that 53.1% of patients with invasive ductal pancreatic carcinoma had DM, and in 45.9% it was thought to be secondary to the carcinoma.[54] Hyperglycemia or DM is present in approximately 85% and 50%, respectively, of patients with pancreatic carcinoma at the time

TABLE 35.4 **Interval Between Diagnosis of Diabetes Mellitus and Diagnosis of Pancreatic Cancer or Date of Examination of Control Population**

Interval Between Diagnosis of Diabetes Mellitus and Pancreatic Cancer	Pancreatic Patients (*n* = 164)	Control Patients (*n* = 60)	P-Value
0	66 (40.2%)	2 (3.3%)	<0.001
1	15 (9.2%)	2 (3.3%)	0.17

of diagnosis. The reasons for this association have been the subject of much speculation. In another study, a diagnosis of diabetes was made in 22.8% of the patients with pancreatic cancer and 8.3% of the control population. In 40.2% of patients with pancreatic cancer the diagnosis of diabetes was made concurrently with the diagnosis of the cancer, and in 15.9% within 2 years before the diagnosis[55] (Table 35.4). In the control population, only 13.3% of the diabetes was of 2 years' duration or less. The greatest percentage of diabetes in the control population was of 10 years' duration or greater (53.3%) (Table 35.4). These data further support the idea that DM predisposes to the development of pancreatic cancer in a small number of patients, but that pancreatic cancer causes the development of DM in most patients. Possible mechanisms by which pancreatic cancer could contribute to the development of type 2 diabetes include: (1) destruction of islets, (2) impairment of the insulin secretory mechanism, (3) development of insulin resistance, and (4) tumor-related pancreatitis. Insulin and C-peptide measurements during OGTTs in patients with pancreatic cancer have shown abnormal β cell function with reduced plasma C-peptide responses in 50% of patients, as well as increased plasma proinsulin–to–C-peptide ratios.[56,57] Insulin resistance has been demonstrated in most patients with pancreatic carcinoma.[58-60] Morphometric studies of tumor-free regions of the pancreas have shown reduced β cell populations.[61] An inverse correlation was noted between the number of β cells and the FPG concentration. These data indicate that pancreatic cancers produce substances or responses that destroy normal β cells.[59-62] The presence of diabetes in patients with pancreatic cancer predicts that the tumor is less likely to be resectable,[63] and the patient has a poorer prognosis for disease-free and overall survival than if diabetes is not present.[63,64] Patients with pancreatic cancer typically have type 2 diabetes, and most have been treated with oral antihyperglycemic agents.[55,64] Reasons for the poorer survival of patients with diabetes may relate to the mitogenic activity of the higher insulin levels, as well as increases in insulin and insulin-like growth factor-1 receptors in the tumors.

Several intriguing observations that were reported recently make this relationship between pancreatic cancer and DM even more complex and confusing. Li and associates reported that metformin treatment of diabetic patients was associated with a decreased risk for developing pancreatic carcinoma, whereas insulin or insulin secretagogue treatment was associated with an increased risk.[65] Metaanalyses of survival outcomes in metformin-treated patients with pancreatic cancer present conflicting data.[66] One metaanalysis of two studies involving 181 patients showed no benefit of metformin treatment. In contrast, a metaanalysis of eight cohorts involving 2805 patients showed an improvement in overall survival at 6 months.[66] In a large multicenter clinical trial that compared the treatment of type 2 diabetic patients treated with rosiglitazone-based therapy versus metformin plus sulfonylurea therapy, the development of pancreatic cancer during the study was statistically less frequent in the rosiglitazone arm than in the active comparator arm (two cases vs. 13 cases; $P < .007$).[67]

Islet autotransplantation in pancreatic resection for pancreatic carcinoma has not been a generally accepted procedure because of the concern of introducing tumor cells carried along with the islets during the purification process. Balzano and coworkers recently reported the results of islet autotransplant in 14 patients with pancreatic or periampullary adenocarcinoma.[68] Eleven were disease-free at a median follow-up of 725 days, and none had tumor recurrence at the transplantation site. Further studies and better methods of islet purification will be necessary for this procedure to become more acceptable.

KEY POINTS

- Pancreatic ductal carcinoma is increasing worldwide and is the third or fourth most common cause of cancer deaths in the United States. Because it is diagnosed late in its course, 5-year survival rates range from 1% to 8%. Type 2 diabetes occurs in 68% of patients with pancreatic ductal carcinoma compared with 20% in age- and sex-matched patients with other carcinomas. Patients with long duration of type 2 diabetes have an increase in pancreatic cancer (1.6-fold), comparable to that of other cancers. However, type 2 diabetes occurring in the 2- to 3-year period before the diagnosis of pancreatic cancer is 5- to 8-fold higher than diabetes diagnosed during a comparable 2- to 3-year period in matched control patients. These data, plus the observations that diabetes frequently improves after tumor resection, indicate the involvement of pancreatic cancer in the pathogenesis of new-onset diabetes mellitus. The development of new-onset diabetes mellitus associated with weight loss should be an alert to evaluate the patient for pancreatic ductal cancer and make the diagnosis several years before symptoms from the cancer itself.

Autoimmune Pancreatitis

Autoimmune pancreatitis (AIP) is a steroid-responsive pancreatic fibroinflammatory disease that has been recognized with increasing frequency since 1995. The disease is associated with infiltration of immune cells into pancreatic tissue, and the disease responds dramatically to corticosteroids. Two subtypes have been identified.

Type 1 AIP is an IgG-4–related disease and is characterized by elevated serum IgG-4 levels and IgG-4–producing plasma cells infiltrating the pancreas.[69] It is the most frequent subtype and affects patients in their 60 and 70 years of life. Obstructive jaundice was the presenting symptom in 75% of the patients in a series of 731 AIP patients. IgG-4 accounts for less than 5% of the total serum IgG in healthy individuals and is ordinarily present at less than 140 mg/dL.[70] The median IgG-4 level in one series of patients with AIP was 663 mg/dL compared with 51 mg/dL in healthy age- and sex-matched controls. Type 1 AIP is frequently associated with involvement of other organs such as proximal biliary tract, kidney, salivary gland, lacrimal gland, and retroperitoneum. Although it responds to steroid therapy, the risk of recurrence on treatment is high. Patients with type 1 AIP have a variety of circulating autoantibodies. Late stages of type 1 AIP lead to exocrine and endocrine failure resulting in steatorrhea and DM.

Type 2 AIP is a pancreatic specific disorder not associated with IgG-4.[71] It accounts for approximately 10% to 20% of AIP patients and affects younger patients (third to fourth decade). Its only extrapancreatic organ involvement is inflammatory bowel disease, which occurs in approximately 30% of patients.[71] In the previously mentioned cohort of 731 patients with AIP, abdominal pain was the presenting symptom in 68% of patients with type 2 AIM.[70] The response rate to steroid therapy is very high, with a low risk of recurrence.

AIP is common in old age and is often associated with DM (33%–78%). In one series from Japan, 30 of 69 patients (46%) with AIP were diagnosed as having DM.[72] In 17, the diagnoses of DM and AIP were made simultaneously, and in 13 the diabetes was preexisting. Twenty-four of the patients were treated with prednisone 0.6 mg/kg body weight/day and gradually tapered over 3 months to a maintenance dose of 5 mg/day, which was maintained for 1 to 3 years. All of them responded well, with improvement in radiologic and serologic parameters. After 3 months of steroid therapy, 6/11 with simultaneous onset improved, and 7/13 with preexisting diabetes improved. Improvement was defined as a decrease in HbA1c greater than 0.5%. The improvement continued through 3 years of therapy in 66% and 60% of the new-onset and preexisting cases of diabetes, respectively. In another study in Japan, 47 patients with AIP were treated with steroids.[73] Of those, 33 (70%) had DM. Thirteen patients had improved glucose tolerance, nine had worsening glucose tolerance, and 32 were unchanged during a mean follow-up of 60 months. Some 17 patients had C-peptide response to a 1-mg intravenous bolus of glucagon at 6 minutes measured before and 1 month after starting steroid therapy. The C-peptide response was improved by the steroid treatment. A poor C-peptide response at baseline predicted the need for insulin even during steroid therapy. A good C-peptide response predicted successful diabetes treatment without the need for insulin. Steroid therapy in AIP is effective in treating the diabetes, as well as the other components of the disease.

First-line therapy for AIP is a loading dose of prednisolone (0.4–0.6 mg/kg) for 2 to 4 weeks and tapered by 5 mg every 1 to 2 weeks until the maintenance dose of 2.5 to 5.0 mg daily is reached (usually 6 months). Maintenance therapy is continued up to 3 years. With low-dose steroid treatment or treatment withdrawal the incidence of AIP recurrence has been reported to range from 24% to 52%. Steroid-sparing agents such as immunomodulators or rituximab are effective treatment modalities.

KEY POINTS

- Autoimmune pancreatitis and fibrocalculous pancreatic diabetes are two rare causes of diabetes mellitus that are important to recognize because of their specific treatment issues and their focus on the vulnerability of the exocrine pancreas to pathologic processes, which then secondarily involve the pancreatic islets. It has been recently recognized that genetic variants of genes regulating exocrine secretory processes predispose the exocrine pancreas to a variety of inflammatory and autoimmune triggers. Both variants of autoimmune pancreatitis respond to glucocorticoid treatment and perhaps other immunosuppressive therapies. Little is known about fibrocalculous pancreatic diabetes other than that its clinical features are changing, and its prevalence is decreasing. It is likely that it is caused by an unknown environmental trigger that activates a susceptible exocrine pancreas to an inflammatory state. The high risk for pancreatic cancer is important to recognize.

Hemochromatosis

Hemochromatosis is an autosomal recessive genetic disorder that results in excessive deposition of iron in parenchymal cells of the liver, pancreas, muscle, heart, anterior pituitary gland, and other organs. The clinical diagnosis in the past was made by the findings of DM, hepatomegaly, and skin pigmentation. More recently, it has been recognized through biochemical and genetic testing.[74]

Dietary iron is absorbed only to compensate for loss and, to a limited extent, storage in the liver.[74,75] When dietary iron is taken up by enterocytes, tissue ferritin binds and stores iron in the enterocyte, preventing it from directly entering the bloodstream. Ferroportin allows iron to be transported out of the enterocytes for release into plasma. Once in the plasma, iron is bound to transferrin and delivered to bone marrow for haem synthesis and to the liver for storage. A hepatic peptide, hepcidin, is the key hormone involved in the regulation of iron absorption.[75] Hepcidin interacts with and inactivates the iron export protein ferroportin, which limits the amount of dietary iron entering the plasma from enterocytes, recycled iron from macrophages, and stored iron from hepatocytes. Hepcidin production is regulated by the bioavailability of iron; hepcidin synthesis increases with increased iron storage in the liver, limiting further absorption of iron. Iron deficiency results in downregulation of hepcidin production by the liver, allowing iron absorption to increase.

Hemochromatosis is commonly attributed to the autosomal recessive inheritance of a mutation in the *HFE* gene (type 1 hemochromatosis) encoding a C282Y substitution that results in a deficient or inactive hepcidin.[75] Although this accounts for 80% to 90% of cases of hemochromatosis, several mutations in genes other than *HFE* (including *HIV* and *HAMP, TFR2*, and *ferroportin 1*) have been recently discovered and account for types 2, 3, and 4 hemochromatosis, respectively.[74] The carrier rate for the C282Y-encoding mutation among populations of Northern European ancestry is between 10% and 15%. Heterozygotes may have mildly elevated iron studies but do not develop clinical disease. Even homozygotes may have a variable penetrance of the disease. Additional metabolic abnormalities such as obesity with steatohepatitis or excessive alcohol consumption increase the penetrance and severity of the disease.

The first phenotypic expression of the disease is an elevation in serum transferrin saturation. This abnormality is followed by iron accumulation in the tissues and an elevation in the serum ferritin concentration. Early clinical findings are related to hepatic dysfunction and joint symptoms. Clinical DM and skin pigmentation occur relatively late during the disease. DM has been reported in 50% to 60% of patients with hemochromatosis.[74,76] Another 20% to 30% had glucose intolerance. These figures represent data from older series in which the diagnosis was made late in the disease. DM is more frequent in patients who have a family history of DM.

Follow-up of 237 patients who were given a diagnosis of hemochromatosis and treated at a single center from 1983 through 2005 has provided insights into the natural history of the cirrhosis and DM associated with the disease.[77] Before 1996, hemochromatosis was diagnosed by the classic clinical and laboratory features of the disease. Since 1996, genetic testing, which is now available commercially, made it possible to diagnose hemochromatosis in asymptomatic patients.[78] Of 45 patients diagnosed before 1996, 30.2% had cirrhosis of the liver, and 35.6% had DM. After 1996, 192 patients were given the diagnosis of hemochromatosis (34% by family screening and 40% by clinical suspicion), only 7.5% had cirrhosis of the liver, and 17.7% had DM at the time of diagnosis. It is obvious that early diagnosis through genetic testing and effective treatment can significantly reduce development of the complications of hemochromatosis. The established treatment for hemochromatosis is frequent phlebotomies to reduce the iron stores. Of note is the observation that performing phlebotomy and reducing tissue iron in well-established clinical disease did not improve diabetes or lessen its management requirements. Thus, early diagnosis and treatment is primarily preventative.[78]

The metabolic studies that have been done show that patients with hemochromatosis have marked insulin resistance.[76] Histologic study of the pancreas shows iron deposits that are greatest in the acinar cells but do involve islet cells.[74] Insulin secretion in response to glucose or arginine is decreased; however, glucagon secretory responses to arginine are increased and unaffected by glucose.[76] The data are compatible with a marked reduction in β cell function and no disturbance in α cell function. The hyperglycemia is a result of insulin resistance and decreased β cell function.[76] The prevalence of DM probably could be reduced by early diagnosis of hemochromatosis and initiation of phlebotomy therapy.[74] Therapy for patients with hemochromatosis and clinical diabetes frequently requires insulin (40%–50% of patients), although no systematic studies of therapy have been done.[76] Reduction of tissue iron stores, although most beneficial in the early stages of disease, nonetheless can help improve glycemic control in 35% to 45% of patients.

Hemosiderosis

Excessive iron deposition occurs in a variety of conditions other than primary hemochromatosis. In thalassemia major, frequent blood transfusions are necessary and may lead to massive iron overload. The reported prevalence of DM in treated thalassemia major is approximately 16%. This figure is highly correlated with the number of blood transfusions given and the duration of the disease. The incidence of IGT is reported to be 60%.[79] Further evidence that deposits of excess tissue iron themselves are responsible for many of the metabolic abnormalities seen in hemochromatosis and thalassemia major comes from studies in rural male Bantus.[80] Many Bantus drink alcoholic beverages that are brewed in iron containers and ingest in excess of 100 mg of iron per day. In those individuals, the prevalence of DM is 10-fold higher than in nonalcoholic beverage–consuming rural Bantu males.

Mechanistic studies in patients with thalassemia major with normal, impaired, and diabetic glucose tolerance tests show that increased iron stores are associated with the development of insulin resistance and a delay in early insulin secretion.[81] A correlation between increased iron stores in normal women and the development of type 2 diabetes was demonstrated recently in the Nurses' Health Study.[82] Several large epidemiologic studies have shown that high body iron stores are associated with an increased risk for developing type 2 diabetes. In a prospective cohort of 1613 males in the Kuopio Ischemic Heart Disease Risk Factor study, type 2 diabetes developed in 331 cases during a 16.8-year follow-up.[83] Baseline serum ferritin was 191 μg/L in those who developed type 2 diabetes compared with 151 μg/L in those who remained nondiabetic. This represented a 14% increase in diabetes for each 100-μg/L increase in serum ferritin. Similar findings were found in 27,548 individuals in the European Prospective Investigation into Cancer and Nutrition–Potsdam study,[84] where after adjustment for all known risk factors, those in the highest quintile of serum ferritin concentrations had a relative risk for type 2 diabetes of 1.73 compared with those in the lowest quintile. No significant association was found for the soluble transferrin receptor.

KEY POINTS

- Diabetes mellitus (DM) associated with hemochromatosis and hemosiderosis is caused by deposition of iron into the pancreatic islet cells. The iron causes death of the islet β cells which lead to progressive decreases in insulin secretion. Glucagon secretion seems to be little-affected. Iron deposition in liver, muscle, and other tissues causes insulin resistance. Hemochromatosis is a genetic disorder involving the hepcidin gene (*HEF1*) or non-*HEF1* genes that regulate iron absorption. The clinical manifestations are bronze coloration of the skin, hepatic cirrhosis, and diabetes. The diagnosis now is made by genetic testing of susceptible individuals. The prevalence of DM depends on the time of diagnosis. Those diagnosed by genetic testing have a prevalence of DM of 18%, whereas in those diagnosed by clinical criteria it is 36%. The treatment of hemochromatosis is frequent phlebotomies. Early treatment can reduce the development of DM, but once it develops it cannot decrease, although the management of hyperglycemia is easier. Hemosiderosis is caused by frequent blood transfusions such as occur in thalassemia major. The prevalence of DM in hemosiderosis is approximately 16%. Treatment of DM in hemosiderosis or thalassemia is insulin.

Cystic Fibrosis

Cystic fibrosis (CF) is a monogenetic disorder with abnormal cyclic adenosine monophosphate-regulated chloride channel activity. It is an autosomal recessive genetic disease with an incidence of 1 in 2500 live births in White populations. CF affects over 90,000 individuals, and they are heterogeneously distributed worldwide. Over 2000 mutations have been identified in the *CFTR* gene. Approximately 440 are disease-causing. *CFTR* mutations are categorized into five groups: class I mutations are associated with the more severe phenotypes ,and class V the milder phenotypes. The F508del is the most prevalent CF-causing mutation, affecting approximately 82% of the CF population. It is associated with deletion of phenylalanine at position 508. There is a strong association between the *TCF7L2* genotype and the risk for CF-related diabetes (CFRD).[85,86] The disease-causing mutations result in thick, sticky mucous secretions in mucous-producing organs such as lung, exocrine pancreas, large and small intestine, hepatobiliary system, and sweat glands. Failure to secrete sodium, bicarbonate, and water leads to retention of enzymes in the pancreas, and ultimately to destruction of pancreatic tissue. Histologic examination of the pancreas in patients with CF shows fatty infiltration, necrosis, and fibrosis of the exocrine pancreas. Islet cell architecture is disrupted, and the absolute number of pancreatic islets is diminished. Islets that are present show significant decreases in β cells, α cells, and pancreatic polypeptide-producing cells and increases in δ (somatostatin-producing) cells. Islet amyloid deposits have been found in 69% of diabetic CF cases examined.[87-89]

CFRD is a severe complication of CF and has increased in prevalence as patient survival has increased from 8 years of age in 1970 to 40 to 50 years of age at the present time.[87-89] The prevalence of CFRD increases from 2% in childhood, to 20% in adolescence, to 40% to 50% in adults. The presence of CFRD impacts survival in patients with CF: fewer than 25% of patients with CFRD survive to an age of 30 years compared with 60% of CF patients with normal glucose tolerance.[87-89]

DM requiring medical therapy (usually insulin) has been reported in 4.9% of patients of all ages with CF in a large European study of 1348 patients and in 5.1% of 18,627 patients of all ages monitored at CF centers in the United States and Canada. Diabetes occurs more often in individuals who are homozygous for the most common CF mutation, F508del. Diabetes has been reported in 32% of Danish patients who were older than 25 years of age. Routine OGTTs suggests that, of the total CF population 5 years of age or older, 35% have normal glucose tolerance, 37% have IGT, 17% have CFRD without fasting hyperglycemia, and 11% have CFRD with fasting hyperglycemia.[87,88,90]

The primary defect in CFRD is a reduced and delayed insulin secretory response to carbohydrates that starts in childhood, progresses over time, and results in a 50% prevalence of DM in CF patients over 35 years of age. The decrease in islet cell function is secondary to the exocrine pancreatic insufficiency, as the glucose and insulin responses to oral glucose in CF patients are normal until there is exocrine deficiency.[91] Recent data indicate that defective β cell CFTR protein also plays a role in reducing insulin secretory function. This pattern of insulin insufficiency spares basal insulin secretion and results in a glucose abnormality characterized by normal FPG and postprandial hyperglycemia. Late in CFRD, total insulin, glucagon, and pancreatic polypeptide secretions are decreased. First-phase insulin secretion after intravenous glucose is markedly reduced in patients with CF compared with matched controls. The pattern of abnormal glycemia is normal plasma glucose before breakfast with abnormal postprandial glucose rises that are highest after the evening meal.[85,87,88]

Peripheral insulin sensitivity is usually normal or increased in CF patients, but serious infections and systemic corticosteroid treatment increase insulin resistance. Insulin resistance occurs later as IGT and diabetes develop, and patients experience additional complications related to their CF.

The delay in insulin secretion commonly results in hypoglycemia, even in individuals who do not have CFRD. Among children and adolescents with CF, 13% experience hypoglycemia during routine OGTTs, and this represents a mismatch between the prompt absorption of an oral glucose solution and delayed first-phase insulin secretion in CF. Ketosis is rare.[90]

Registry studies from the 1980s and 1990s showed significant increases in mortality in CF patients who developed CFRD, even after adjustment for other risk factors. In adults, overall mortality was double in patients with CFRD compared with CF patients without DM. Earlier diagnosis and treatment have been shown to decrease mortality in patients with CFRD: comparing cohorts for 1992 to 1997 and 2008 to 2012, age-adjusted mortality for individuals with CFRD fell from 4.9 to 1.8 per 100 person-years. Infection rates are increased, and lung function declines more quickly in people with CFRD. Although the risk of microvascular complications occurs as in other forms of diabetes, the main reason for treatment is to prevent deterioration in lung function and weight loss. Several studies have shown that weight loss and increasing pulmonary function deterioration are observed several years before the diagnosis of CFRD, indicating that early changes in insulin secretion and glucose metabolism hasten the clinical course of CF. The evidence that glucose abnormalities that do not fulfill the diagnostic criteria for diabetes can significantly impact clinical status influences the decision to treat CFRD. Treatment may therefore be required at an earlier stage in CFRD than for other types of diabetes.[85,88]

The recommended diagnostic criterion for CFRD is a 2-hour plasma glucose of 11.1 mmol/L or more in an OGTT. Neither FPG nor a HbA1c is reliable to diagnose CFRD. Screening is recommended to start at 10 years of age. More recently, it has been proposed to use CGM for diagnosis. In people with CFRD undergoing CGM, glucose was detected in airway secretions when blood glucose levels rose above 8 mmol/L. This level was exceeded for 45% of the day in those with CFRD, compared with 6% of the day in people with CF and normal glucose tolerance.[85,87,88]

Hyperglycemia in patients with CF can be intermittent or permanent. Intermittent hyperglycemia occurs with glucocorticoid therapy, infection, or stress and must be treated with insulin until it resolves. Permanent hyperglycemia is always treated with insulin. It is likely that patients with CF progress from intermittent hyperglycemia to permanent hyperglycemia as pancreatic destruction continues to occur.

Treatment of CFRD consists of a high-calorie, low–simple carbohydrate diet. Many people with CF take pancreatic enzymes to improve food- and fat-soluble vitamin absorption and to prevent steatorrhea. Active, but not total, glucagon-like peptide-1 (GLP-1) plasma levels are decreased in CF patients and tend to be even lower in patients with CFRD. Pancreatic enzyme replacement improves GLP-1 secretion. People with CF have rapid gastric emptying.[86-89]

Oral sulfonylureas and other antidiabetic agents have been tried for treatment of CFRD; however, the treatment of choice for the postprandial hyperglycemia is short-acting insulin before meals. Treatment with insulin has been associated with up to 22-mmol/mol (2%) improvement in HbA1c after 1 year's treatment, and 11-mmol/mol (1%) improvement after 5 years.[87,90] Improved glycemic control is associated with improvements in body weight (BMI improvement of 1–3 kg/m^2) and lung function (6%–35% increased forced expiratory volume in 1 second).[88-90] Insulin therapy may also lead to a reduction in the frequency of chest infections, although this has not been demonstrated in all studies. There is no convincing evidence to support the use of any insulin regimen. Of the 10,810 people recorded in the CF Foundation Patient Registry for 2015, 1982 (18.3%) were receiving diabetes treatment.[85,88-90]

Specific treatment for CF requires replacing the specific mutant gene by modifying it to a non–disease-causing mutation. This would be a formidable task, as the gene is expressed in so many tissues. A more feasible approach is to determine the process by which the mutant gene acts to create the abnormally functional CFTR protein and create small molecules that can be administered to patients that can improve the defect responsible for the poor function of CFTR. This is the process that has been and is being pursued. The new therapeutic agents being used to treat CF are classified by their action on specific abnormalities of CFTR generated by the gene mutations.[92] They include:

1. Potentiators: restoring the channel gating and conductance. Around 5% of CF-causing mutations lead to impaired CFTR channel gating or conductance as primary defects (classes III and IV).
2. Correctors: rescuing the protein folding, processing, and trafficking. Most CF patients carry a mistrafficking CFTR mutation such as F508del, which is the most prevalent CF-causing mutation (class II).
3. Stabilizers: rescuing the protein stability at the plasma membrane. Although certain CFTR mutants are functional and present at the plasma membrane, the protein may still display a significant reduction in half-life (class VI).
4. Read-through agents and nonsense-mediated mRNA decay inhibitors: rescuing the protein synthesis. A significant fraction of the CF-causing mutations are in-frame nonsense, frameshift, and splicing variants that introduce a premature termination codon into the *CFTR* mRNA, thus abrogating CFTR protein synthesis or resulting in translation of shortened, truncated forms (class I).
5. Amplifiers: increasing the abundance of protein substrate. Some CF-causing mutations lead to reduction in the synthesis or maturation of the CFTR protein.
6. Antisense oligonucleotides (ASOs): correcting the aberrant splicing and more. ASOs are chemically modified synthetic RNA-like molecules that act by complementary base pairing to the target sequence. ASOs have been demonstrating promising results to correct nonsense and splicing mutations, or even to replace missing bases caused by deletion mutations such as F508del.

Ivacaftor is one of the new modifiers that have been developed to treat some forms of CF. It partially reverses the effects of the mildest mutations in CF (gating mutations); there are newer agents in development with effects on the more severe mutations. Ivacaftor is being evaluated for its effects on glucose metabolism and insulin secretion in patients with CF to determine its potential for the prevention and/or treatment of CFRD. A study of five people with CF (three with normal glucose tolerance, one with recent diagnosis of CFRD, and one with CFRD for 16 years) showed that, after 1 month's treatment with ivacaftor, the insulin response to oral glucose improved by 66% to 178%, except for the individual with longstanding diabetes, who showed no improvement. A recent study of 12 CF patients with a median age of 13.8 years, seven of whom had a normal OGTT, four of whom had IGT, and one with a 1-hour OGTT glucose greater than 155 mg/dL evaluated the effects of 4 months' treatment with ivacaftor on glucose, insulin, and incretin plasma levels following oral glucose and meal stimulation and an intravenous arginine test. Insulin secretion improved; however, plasma glucose and incretin levels were not improved.[93] The mechanism for the improvement in plasma insulin is not understood but points to a role of the CFTR modulators in the regulation of insulin secretion by the β cell. The duration and clinical benefit of this effect on insulin secretion in this very young CF population needs to be investigated.

Microvascular complications have been observed in patients who had CFRD with fasting hyperglycemia for longer than 10 years. Fourteen percent had microalbuminuria, and 16% had retinopathy. Macrovascular disease appears to be quite uncommon.

KEY POINTS

- Cystic fibrosis–related diabetes (CFRD) is a form of diabetes that occurs in individuals with mutations of the cystic fibrosis transmembrane conductance regulator gene. The result of these mutations is an abnormal cyclic adenosine monophosphate–regulated chloride channel, which causes mucous secretions to be abnormal and very viscous, such that they block pulmonary bronchi, pancreatic ducts, and other secretory channels. The results are chronic and progressive pulmonary disease, as well as pancreatitis and DM. The destruction of islets and deficient β cell insulin secretion start at birth and increase with the duration of the disease. The prevalence of CFRD increases from 2% in childhood, to 20% in adolescence, to 40% to 50% in adults. The presence of CFRD impacts survival in patients with cystic fibrosis: fewer than 25% of patients with CFRD survive to an age of 30 years, compared with 60% of CF patients with normal glucose tolerance. CFRD is characterized by relatively minimal fasting hyperglycemia with marked postprandial hyperglycemia. Treatment is directed toward treating the postprandial hyperglycemia. Treatment of hyperglycemia should commence as early as possible, as hyperglycemia hastens pulmonary decline.

HYPERGLYCEMIA ASSOCIATED WITH ENDOCRINOPATHIES

In the complex regulation of fuel homeostasis, many hormones other than insulin play a complementary role. Growth hormone (GH), by itself and through stimulating synthesis of IGF-1, controls many aspects of amino acid transport, protein synthesis, and lipid metabolism. Glucagon and catecholamines are counterregulatory hormones that protect against hypoglycemia and provide extra glucose when needed during stress states. Glucocorticoids have both a permissive role in the normal physiologic regulation of gluconeogenesis and a pharmacologic role in providing increased glucose availability during stress. Somatostatin is a paracrine hormone that appears to act locally to help regulate the normal secretory patterns of GH, insulin, glucagon, and several gastrointestinal hormones.

The mechanisms responsible for the action of these various hormones are described in detail in other chapters.

This section will address the unique characteristics of hyperglycemia as it relates to each endocrinopathy, as well as its treatment.

Acromegaly

Acromegaly is characterized by excessive and autonomous secretion of GH and IGF-1. The disease has usually been present for a mean of 7 years at the time of diagnosis. According to the current consensus guidelines, acromegaly is diagnosed if IGF-1 levels are above the age-adjusted normal range and the GH nadir during an OGTT is higher than 0.4 μg/L.[94-96] The prevalence of overt DM reported in different series of acromegalic patients ranges from 10.5% to 52.6%. IGT may be present in as many as 36% of acromegalic patients. Less than 30% of patients with acromegaly are normoglycemic.[97,98] The prevalence of DM in acromegalic patients is a function of increasing age, higher BMI, longer duration of untreated acromegaly, and the genetic predisposition of the corresponding nonacromegalic population to develop DM. Approximately 20% of newly diagnosed patients with acromegaly have DM, and undiagnosed acromegaly is present in 0.5% to 3% of patients being followed for type 2 DM. The onset of DM can precede the diagnosis of acromegaly by 1 to 3 years, as well as following its clinical diagnosis. Successful treatment of acromegaly has been reported to result in a remission of the diabetes in 23% to 58% of the patients. The longer the acromegaly is untreated, the less likely it is that remission will occur with treatment.

Elevated GH and IGF-1 levels cause increased adipose tissue lipolysis and insulin resistance, which results in excessive hepatic glucose production and impaired insulin-mediated muscle and adipose tissue glucose uptake. Insulin resistance is correlated with circulating IGF-1 levels and has been demonstrated by the euglycemic hyperinsulinemic clamp and the minimal model techniques.[94,97]

The primary treatment for acromegaly is transsphenoidal surgical removal of the tumor producing GH or GH-releasing factor. Surgical remission is defined as a random or a nadir GH level in an OGTT less than 1.0 μg/L and a normal age-matched IGF-1 level 3 months after surgery. This is achieved in approximately 50% of patients, with total tumor resection being more common in microadenomas (75%–95%) than in macroadenomas (40%–69%). Thus, in general, half of the patients will require adjuvant treatment to achieve remission. Although not supported by clinical follow-up, some consensus groups suggest that a nadir GH level during an OGTT using newer, higher-quality assays of 0.4 μg/L should be the value used to define remission.[99]

Medical therapy is recommended for patients with persistent disease after surgical resection of the adenoma, as well as for patients in whom surgery is not appropriate. Adjuvant medical treatment use consists of three drug classes: somatostatin receptor ligands (SRLs), dopamine agonists (DAs), and GH receptor (GHR) antagonists.[96,99]

The SRLs (octreotide LAR and lanreotide autogel) have been considered the first-choice medical treatment.[94,95,99] These drugs act through targeting somatostatin receptor subtype 2 and, to a much lesser extent, receptor subtype 5, leading to a decrease in GH secretion and tumor shrinkage. Approximately 40% to 50% of patients treated with these drugs achieve full biochemical control of acromegaly. For patients receiving medical treatment, disease control is defined as a normal age-matched IGF-1 level. The GH nadir in the OGTT has a low accuracy and should not be used, as SRLs interfere with the feedback of glucose. The multireceptor-targeted SRL pasireotide differs from the other SRLs owing to its higher affinity for somatostatin receptors 3 and 5. It is more effective than other SRLs and has a broader range of activities (suppression of incretin secretion, greater inhibition of insulin secretion, and some suppression of glucagon secretion). In a randomized prospective study, disease control with pasireotide was achieved in 20% of patients whose disease was uncontrolled after treatment with octreotide LAR or lanreotide autogel.

The DA cabergoline acts by binding to dopamine-2 receptors. It has a lower efficacy than other drug classes (~20%–30% as a monotherapy and 30%–35% in combination therapy with SRLs), and some patients present treatment escape during long-term therapy. Cabergoline can be used as an adjuvant treatment, particularly for patients with mild disease (IGF-1 levels up to 1.5-fold the upper limit of the normal range).[95,99]

Pegvisomant (PEG) is a GHR antagonist that binds to peripheral GHRs without activating the intracellular signaling pathways. PEG has no action on somatotropin-producing pituitary tumors. It is the drug with the highest efficacy in controlling acromegaly, with success rates ranging from 63% to 97%, depending on the study. PEG has been increasingly used as first-line monotherapy or in combination with SRLs or cabergoline.[99]

Radiotherapy is effective at controlling tumor volume in 90% of cases and leads to biochemical control in approximately 60% of cases, but GH normalization takes several years. Although highly effective, radiotherapy is associated with many significant long-term side effects. Radiotherapy is considered a third-line therapy and is reserved for patients with aggressive tumors that are resistant to surgical and medical treatment.[94,95,99]

Surgical removal of GH-secreting pituitary tumors improves both glucose tolerance and diabetes. Insulin secretion and sensitivity improve within 1 to 2 months after surgery, and normalization of glucose homeostasis occurred in 23% to 58% of patients with preexisting diabetes, depending on the cohort studied. Long-term response data are not available, particularly in subjects in whom cure of acromegaly and/or improved β cell function was not achieved.[95,99]

Use of medical treatments (SRL, GHR antagonist, DA) as primary therapy or to supplement prior inadequate surgical treatment has allowed attainment of greater and more consistent normalization in circulating GH and IGF-1 levels (77%). Normalization of IFG-1 in acromegalic patients with DM results in a 30% remission of the diabetes and easier management of the remainder. Treatment of acromegalic patients with SRLs presents several issues with respect to glucose metabolism. Reductions in circulating GH and IGF-1 levels will decrease insulin resistance and should lead to improvement in glycemic control in subjects with DM-related IGT. However, pharmacologic doses of SRLs also reduce insulin secretion (decreased insulinogenic index), and such a reduction should cause a deterioration in glucose tolerance. In a specific patient, SRL therapy will modify glucose metabolism as an interaction of these competing effects.[99]

Approximately two-thirds of acromegalic patients with DM are treated with insulin, and one-third are treated with oral hypoglycemic agents. SRL treatment in patients with DM and acromegaly frequently leads to improvement in glycemic control, as measured by a reduction in the insulin dose, conversion from insulin therapy to oral hypoglycemic agent therapy, or conversion from oral hypoglycemic agent therapy to dietary management. Some patients (those with more severe insulin deficiency), however, will have significant deterioration in glycemic control. When high doses of SRLs are given to acromegalic patients with normal glucose tolerance, IGT and even frank DM (at rates as high as 20% and 29%, respectively) may develop.[95,99]

An alternative to treatment with SRLs is treatment with the GHR blocker PEG. This agent decreases IGF-1 production and improves glycemic control. In contrast to SRLs, it increases GH secretion and has no inhibitory effects on insulin, glucagon, or incretin secretion. However, it causes an increase in visceral fat and occasionally is associated with increased liver enzymes.[95,99]

Appropriate treatment for acromegaly is necessary to reduce the increased mortality that has been seen in the past. This increased mortality is attributed to cardiovascular, cerebrovascular, and neoplastic diseases. The best determinants of outcome in acromegalic patients are age at diagnosis, interval between symptoms and diagnosis, and mean long-term circulating GH and IGF-1 levels. Because insulin resistance and DM contribute significantly to cardiovascular risk, aggressive diagnosis and management of the DM associated with acromegaly are essential.

Growth Hormone Treatment

The availability of recombinant DNA technology to make human GH has provided an opportunity to treat many GH-deficient individuals. One consideration in treatment with recombinant human GH is the question of whether long-term treatment leads to the development of DM. A recent study of glucose metabolism in 22,311 children and adolescents treated with human GH and followed for a mean of 4.2 years found a 3.8-fold greater frequency of type 2 diabetes (16.8 cases per 100,000 years of GH treatment) than predicted.[100] Thirteen of the 18 patients had risk factors for diabetes. The frequency of type 1 diabetes was the same as expected. A French study of 5100 children treated with GH and evaluated at 30 years of age (mean follow-up 15 years) had the same prevalence of treated diabetes (oral drugs or insulin) as the general population of France.[101] The data suggest that GH treatment accelerates the development of type 2 diabetes only in those individuals who have risk factors that predispose to the development of type 2 diabetes.

Glucocorticoid Effects on Glucose Metabolism and Corticosteroid-Mediated Diabetes Mellitus

Glucocorticoids are insulin antagonistic hormones. When administered in pharmacologic doses, they increase hepatic gluconeogenesis, decrease muscle glucose uptake and glycogen synthesis, increase muscle proteolysis, and increase adipose tissue lipolysis.[102,103] Compensatory insulin secretion that should increase as a consequence of insulin resistance is blunted by glucocorticoid modulation of gene expression in β cells, which causes a decrease in cytoplasmic calcium stimulation of insulin secretory granule exocytosis.[102,103] Additionally, short-term exposure to glucocorticoids reduces the insulinotropic effects of GLP-1. A consequence of these pharmacologic effects is glucocorticoid-induced glucose intolerance, the magnitude of which is dependent on the dose and duration of glucocorticoid exposure. When sustained pharmacologic concentrations of glucocorticoids occur in normal individuals, the compensatory increase in insulin secretion maintains FPG within the normal range, but the postprandial plasma glucose concentration is elevated above normal in 25% to 90% of such individuals.[102-104] Fasting hyperglycemia would be expected in individuals with limited baseline β cell insulin secretory reserve, as occurs in individuals genetically susceptible to type 2 or other forms of β cell–deficient diabetes.

Exogenous steroid use involves as much as 1% of the general population; 40% of this is for respiratory diseases, and the remainder is split between antiinflammatory and immunosuppressive purposes.[104] Two types of exogenous steroid treatment regimens prevail: high-dose administration for a limited period followed by a slow downward titration and prolonged low dose/discontinuation, or high prolonged maintenance dose for severe diseases. The odds ratio for development of steroid-induced new-onset DM is reported to be 1.36 to 2.31.[104] Among renal transplant recipients receiving long-term corticosteroid therapy, steroid-induced DM has been reported to develop in as little as 5.5% to as much as 46% of patients.[103,104] Factors that influence the development of DM during corticosteroid therapy include a family history of DM, increasing age, obesity, and both average daily and total cumulative corticosteroid dose. In individuals with a previous onset of DM, administration of glucocorticoids significantly worsens glycemic control and requires modification of diabetes management.

Some insight into the mechanisms by which glucocorticoids cause DM was obtained by investigating the effects of administration of dexamethasone on oral glucose tolerance, on glucose turnover under basal conditions and during glucose infusion, and on the insulin response during hyperglycemic clamp studies in normal individuals who had been characterized previously as low insulin responders or high insulin responders.[105] Dexamethasone caused a higher FPG concentration, a greater rise in plasma glucose, and a lesser rise in plasma insulin during the OGTT in the low insulin responders than in the high insulin responders. A diabetic OGTT result was obtained in three of the six low and none of the six high insulin responders. Dexamethasone increased hepatic glucose production only in the low insulin responders and increased insulin secretion during the hyperglycemic clamp study only in the high insulin responders. The conclusion drawn from these studies is that type 2 diabetes develops when plasma glucocorticoids are elevated in individuals with limited β cell secretory function.

Steroid-induced diabetes may be permanent or transient. In general, insulin is required for treatment if the FPG concentration exceeds 180 mg/dL. At lesser levels of fasting hyperglycemia, many physicians treat the hyperglycemia with oral hypoglycemic agents. Few studies have adequately evaluated the efficacy of pharmacologic treatment of steroid-induced DM. Because insulin resistance is a major abnormality, perhaps a combination of insulin sensitizers and insulin would be most effective.[106,107] A recent 14-day study in men with metabolic syndrome assessed the benefit of coadministration of a DPP-4 inhibitor (sitagliptin) with prednisone in preventing the diabetogenic effects of glucocorticoid administration. The concomitant administration of the DPP-4 inhibitor improved various aspects of pancreatic islet-cell function but did not prevent the prednisone-induced increment in postprandial glucose concentrations.[107] A 4-week randomized study of patients receiving glucocorticoids showed that metformin prevented the deterioration of glucose effects during OGTT as compared with placebo treatment.[107] A reduction in corticosteroid dose improves glycemic control and, in some individuals, may even reverse the diabetes. The more severely elevated the FPG concentration, the less likely it is that reducing corticosteroid levels will reverse the diabetes. Ketoacidosis is very uncommon with steroid-induced diabetes or Cushing syndrome. Hyperosmolar nonketotic coma, however, is not uncommon.

Cushing Syndrome

Depending on the reported patient population, 20% to 45% of patients with Cushing syndrome have DM, and another 10% to 30% have impaired glucose metabolism, meaning that the overall prevalence of abnormal glucose metabolism can be as high as 70%.[108,109] Because FPG is a late manifestation of glucocorticoid-mediated glucose abnormalities, FPG may be insufficient to diagnosis diabetes in more than 50% of Cushing syndrome patients. Age, genetic predisposition, lifestyle, cortisol secretory rate, and duration of cortisol excess are major risk factors for development of DM in Cushing syndrome. Treatment of the Cushing syndrome results in remission of diabetes in some patients and improvement in the remainder.

The recommended first-line therapy for pituitary-mediated Cushing syndrome (Cushing disease) is resection of the pituitary adenoma. The remission rate ranges from 65% to 90%, with a risk of recurrence at 10 years of between 10% and 20%.[108,110] When surgery is not possible or has only been partially successful, pharmacologic agents are used to control the hypercortisolism and the diabetes. The medical therapies that have been used are somatostatin analogues, DAs, and adrenal steroidogenesis inhibitors (ketoconazole, metyrapone, mitotane, and etomidate).[108,111,112] Each has its own issues with effectiveness and safety concerns. Carbergoline, a DA, decreases the prevalence of diabetes and glucose intolerance by 60% and 46%, respectively, in patients with pituitary Cushing syndrome. The long-acting somatostatin analogu octreotide LAR and lanreotide autogel are not effective in normalizing hypercortisolism in patients with pituitary Cushing syndrome and can worsen diabetes by inhibiting β cell insulin secretion. Pasireotide, a multireceptor somatostatin analog, may be effective in treating the endogenous hypercortisolism, but it has been shown to cause hyperglycemia and worsen diabetes by its effect in inhibiting insulin secretion. Mifepristone, a glucocorticoid receptor antagonist, produces clinical benefits in patients with Cushing syndrome and improves FPG (from 149 to 105 mg/dL) and HbA1c (from 7.43% to 6.29%) in those with diabetes.[109,112]

Adrenalectomy is the therapeutic gold standard for patients with adrenal CS caused by functioning adrenal adenomas. Bilateral adrenalectomy could be performed as a rescue treatment in patients with persistent and severe disease, but this approach causes permanent adrenal insufficiency and carries the risk of corticotroph tumor progression (Nelson syndrome).[108,110] Obviously, bilateral adrenalectomy results in adrenal insufficiency and will require lifelong corticosteroid replacement therapy.

Adrenal-directed drugs reduce cortisol secretion by the adrenal glands.[108,109,112] The therapies most often used or under investigation are ketoconazole, metyrapone, mitotane, etomidate, and LCI699. They can be used in every form of Cushing syndrome and may be highly effective in controlling cortisol excess. Ketoconazole, metyrapone, and LCI699 are dose-dependent reversible inhibitors of adrenal cortisol synthesis, acting on one or more enzymes responsible for adrenal steroidogenesis. Ketoconazole (200–1200 mg daily) improves glycemic control in 30% to 56.3% of patients with Cushing syndrome and DM. At doses higher than 4 g/day, mitotane also has an adrenolytic effect, inducing cellular necrosis, so it is indicated mainly for the treatment of adrenal cancer.

Recent studies have documented that steroid-induced DM occurs in adrenal disorders other than those associated with frank Cushing syndrome.[113] Measurement of oral glucose tolerance in 64 consecutive patients with “nonfunctioning” adrenal adenomas identified normal glucose tolerance in 25, glucose intolerance in 17, and DM in 22, including six patients with previously diagnosed DM. Autonomous cortisol secretion without the clinical stigmata of Cushing syndrome has been recognized recently as preclinical Cushing syndrome. A retrospective study of 63 such individuals found that 17.5% had DM. A cross-sectional study of 90 obese, poorly controlled type 2 diabetic patients found that three had the preclinical Cushing syndrome abnormality.[114] Screening 813 patients without clinical characteristics of hypercortisolism being followed for type 2 diabetes found six patients who failed to suppress cortisol secretion during a 2-day standard 2-mg/day dexamethasone suppression test.[114] Excess IGT and DM have been reported in hypopituitary adults receiving conventional replacement therapy, and may be related to the intermittently higher plasma levels that occur after dosing than would occur under normal hypothalamic-pituitary-adrenal axis function.

The DM associated with Cushing syndrome exaggerates the detrimental effects of the other complications of Cushing syndrome such as cardiovascular disease, osteoporosis, hyperlipidemia, and central obesity, and the recognition and treatment of the hyperglycemia is necessary to improve clinical outcomes.

Glucagonoma Syndrome

Proglucagon is synthesized in the pancreatic islet α cells and the intestinal L cells. Proglucagon is processed in the α cell by prohormone convertase 2 into glucagon and several inactive peptides.[115] In the L cell, proglucagon is processed by prohormone convertase 1 and 3 into oxyntomodulin, GLP-1, and GLP-2.[115] Glucagon plays a primary role in facilitating the uptake of amino acids by the liver and converting them into glucose by gluconeogenesis and urea by ureagenesis. GLP-1 is an incretin hormone, and GLP-2 promotes nutrient absorption through activation of crypt cell proliferation and expansion of small bowel epithelium and, perhaps more importantly, inhibits epithelial apoptosis.[115]

Excess and unregulated proglucagon synthesis occurs in some islet cell tumors. A classic syndrome has been described in individuals whose tumors process this proglucagon into glucagon, resulting in severe hyperglucagonemia. This syndrome was recognized in 1974 and is referred to as glucagonoma syndrome.[116] Features of this syndrome include necrolytic migratory erythema, mild non–insulin-requiring type 2 diabetes, glossitis, angular cheilitis, weight loss, anemia, and psychiatric symptoms. Laboratory studies show markedly elevated plasma glucagon levels and severe hypoaminoacidemia (<25% normal). Glucagonomas are rare, with a reported incidence of 1 per 20 to 200 million population. Several reviews of the literature indicate that most tumors occur in the tail of the pancreas; they have an average tumor diameter of 3.6 cm (but as many as one-third are <2 cm), are malignant in approximately two-thirds of cases and have metastases in other organs in 51% to 54% of patients at the time of diagnosis.[117] The DM is characterized by mild hyperglycemia and is nonketotic. The tumors are relatively slow growing, and the 10-year survival rate is 52% in those with metastases and 64% in those without metastases.

The hyperglycemia is owing to excess glucose production by the liver. The hypoaminoacidemia results from an increase in amino acid clearance by the liver. Necrolytic migratory erythema, glossitis, weight loss, and anemia are a consequence of protein malnutrition.[118] Deep venous thrombosis not associated with coagulation disorders is common.

All components of the syndrome are improved if the hyperglucagonemia can be reduced. Treatment consists of surgical removal of the tumor, followed by hepatic artery embolization if necessary for liver metastases. The tumor cells have abundant somatostatin receptors, and somatostatin analogs are very effective in reducing residual plasma glucagon levels.[117] Cytotoxic agents such as streptozotocin and fluorouracil may be valuable as additional modes of therapy. Zinc and amino acid supplementation have been used to treat the rash but are relatively ineffective if plasma glucagon levels remain very high. Antiplatelet therapy should be used to prevent venous thrombosis. The hyperglycemia, although mild, generally requires treatment with an antihyperglycemic agent. Insulin would appear to be the most appropriate agent, although few or no clinical outcome data are available to support this hypothesis. Treatment of the hyperglucagonemia will ameliorate the hyperglycemia in most cases.

If the proglucagon synthesized by the tumor is defective, or if it is cleaved by prohormone convertase 1 or 3 into intestinal glucagon, GLP-1, or GLP-2, the tumor will be associated with either no hormonal abnormalities or with syndromes related to the active products secreted (hyperinsulinemic hypoglycemia or intestinal symptoms with giant villae), and not with the glucagonoma syndrome.[115]

Somatostatinoma

Case reports of patients with hyperglycemia and a pancreatic tumor containing large quantities of somatostatin first appeared in 1977. One of those patients became euglycemic after complete resection of the tumor. Since that time, it has been recognized that large somatostatin-producing pancreatic tumors may be associated with a clinical syndrome consisting of hyperglycemia, cholelithiasis, steatorrhea, and hypochlorhydria.[119]

Somatostatin-producing tumors arise with approximately equal frequency from the gastrointestinal tract and the pancreatic islets. Duodenal somatostatinomas with and without von Recklinghausen disease are seldom associated with recognizable somatostatinoma syndrome, often contain psammoma bodies, and may be associated with demonstrable metastases at the time of surgery. The clinical features of pancreatic somatostatin-producing tumors are variable, and this variation is related to differences in the quantity and qualitative features of somatostatin variants that are synthesized and secreted by these tumors. Marked differences in the degree to which insulin, glucagon, and GH secretion are affected in various patients with pancreatic somaostatin-producing tumors probably account for some of the variation in the clinical syndrome. Hyperglycemia in patients with pancreatic somatostatinomas can vary from mild to modest hyperglycemia to severe diabetic ketoacidosis (DKA).[119-121]

Somatostatin infusions in humans are associated with a pronounced decrease in bile flow and bile acid secretion and an increase in bile cholesterol saturation. *In vitro*, somatostatin has a direct inhibitory effect on cholecystokinin stimulation of gallbladder contraction. These observations provide a basis for understanding the cholelithiasis and steatorrhea commonly seen with pancreatic somatostatinomas. Additionally, they explain the development of gallstones in 23.5% of acromegalic patients treated with octreotide during the first year of treatment.

The hyperglycemia seen as part of somatostatinoma syndrome most likely is related to suppression of insulin secretion. In some patients, a relative insulin deficiency leads to reduced peripheral glucose utilization without impairing suppression of hepatic glucose production.[122] In more severe suppression of insulin secretion, both features of insulin action are reduced.

Somatostatin-producing tumors are rare, usually asymptomatic or only mildly symptomatic, and frequently remain undiagnosed for many years. The diagnosis frequently is made late, and the prognosis is poor because of extensive metastases. The use of somatostatin receptor scintigraphy improves the ability to detect somatostatinomas earlier. Early diagnosis and surgical removal can lead to cure, but medical treatment has produced questionable results. A recent study suggests that somatostatinomas possess functioning somatostatin receptors, and that octreotide therapy (0.5 mg/day subcutaneously) or other somatostatin analogs can effectively decrease somatostatin production by the tumor and improve diabetes and diarrhea.

Pheochromocytoma

Glucose intolerance occurs in approximately 30% of patients with pheochromocytoma, but overt DM is uncommon.[123] Mechanisms responsible for glucose intolerance include suppression of insulin by α-adrenergic receptor stimulation of β cells; an increase in insulin resistance, probably related to elevated plasma free fatty acid levels; and increased hepatic glucose output as a result of β-adrenergic stimulation of hepatocytes. α-adrenergic receptor blockade improves glucose tolerance and insulin secretion. Removal of the pheochromocytoma restores glucose tolerance to normal in most cases. Treatment of glucose intolerance with antihyperglycemic agents is rarely required.

KEY POINTS

- Excess hormone secretion as occurs in many endocrine diseases will lead to hyperglycemia and an increase in diabetes mellitus (DM). The pathogenesis and dynamics of the hyperglycemia depend on the hormone in excess and the drugs that may be used to treat the excess hormone secretion. Excess growth hormone (GH) and insulin-like growth factor-1 (IGF-1) cause severe insulin resistance and, in patients with limited insulin secretory reserve, cause hyperglycemia and DM. Excess cortisol secretion results in increased glucose production by the liver, peripheral insulin resistance, and some impairment of β cell insulin secretion. Individuals with increased cortisol exposure and normal β cell function will have normal fasting plasma glucose levels but postprandial hyperglycemia. Those with limited β cell reserve will develop DM. The percentage of patients with growth hormone or cortisol excess who develop DM depends on the duration and magnitude of hormone excess. Treatment of the hormone excess will resolve the DM in some patients and ease the management of hyperglycemia in other patients. The use of somatostatin receptor ligands (SRLs) to treat GH excess may improve or worsen hyperglycemia, depending on the competitive effects in reducing GH and IGF-1 versus the reduction in SRL-mediated insulin secretion. Tumors secreting unregulated quantities of glucagon or somatostatin present with unique syndromes, including DM. Tumors secreting catecholamines have minimal effects on glucose metabolism.

Hyperglycemia in Critical Care Patients

The ability of humans to adapt to stress is critical for survival. Stress changes the disposition of energy from an anabolic to a catabolic process to provide the substrates necessary for the individual to combat the stress and activates the inflammatory and immune systems.[124] This is accomplished through activation of the sympathetic nervous system, the release of pituitary hormones, the release of cytokines, and central nervous system activation of recognition and behavioral centers. The shift in energy expenditure results in stress-induced hyperglycemia, utilization of muscle protein for gluconeogenesis, and an increase in adipose tissue lipolysis.[124] Although this metabolic and immunologic activation is beneficial in the short term, an excessive and prolonged response can be detrimental and even fatal.

Critical illness is a life-threatening situation that is generally cared for in an intensive care unit (ICU). Patients who require intensive care for more than 5 days have a 20% risk of death and substantial morbidity. Hyperglycemia is present in almost all patients admitted to an ICU and has been shown to have a predictable effect on morbidity and mortality in these patients.[125] Most patients admitted to an ICU have stress-induced hyperglycemia (no previous history of DM). This hyperglycemia is the result of increased secretion of catecholamines, cortisol, glucagon, and GH in the presence of insulin resistance and impaired insulin secretion. The net effect is an uncontrolled production and release of hepatic glucose, a decrease in glucose uptake by insulin sensitive tissues, and an increased glucose uptake by insulin-independent tissues.[124,125]

In 2001, it was reported that patients who had been admitted to a surgical ICU and treated with intensive insulin therapy (n = 765) reduced mortality during intensive care from 8.0% with conventional treatment (n = 783) to 4.6% ($P < .04$).[126] Conventional insulin therapy consisted of starting a continuous infusion of insulin only if the blood glucose exceeded 215 mg/dL and, if started, maintaining the blood glucose between 180 and 200 mg/dL. Intensive insulin therapy consisted of a continuous infusion of insulin when the blood glucose exceeded 110 mg/dL and maintaining it between 80 and 110 mg/dL. The clinical benefits were seen in those receiving ICU care for greater than 5 days (mortality 20.2% in conventional treatment and 10.6% in intensive treatment). Mortality in those treated in the ICU for 1 to 5 days was no different (1.8% vs. 1.7%). Intensive insulin therapy reduced overall in-hospital mortality by 34%, bloodstream infections by 46%, acute renal failure requiring dialysis or hemofiltration by 41%, the median number of red-cell transfusions by 50%, and critical-illness polyneuropathy by 44%, and patients receiving intensive therapy were less likely to require prolonged mechanical ventilation and intensive care.

In contrast to the initial study in surgical ICU patients, a similar study of intensive insulin therapy in patients in a medical ICU showed that intensive insulin treatment reduced blood glucose levels, but did not significantly reduce in-hospital mortality (40.0% in the conventional-treatment group vs. 37.3% in the intensive-treatment group, P = .33).[127] However, morbidity was significantly reduced by the prevention of newly acquired kidney damage, more rapid weaning from mechanical ventilation, and discharge from the ICU. Among 433 patients who stayed in the ICU for less than 3 days, mortality was greater among those receiving intensive insulin therapy. In contrast, among 767 patients who stayed in the ICU for three or more days, in-hospital mortality in the 386 who received intensive insulin therapy was reduced from 52.5% to 43.0% (P = .009).

The benefit of intensive insulin treatment in ICU patients was not supported by the large multicenter NICE-SUGAR study.[128] Within 24 hours of admission to an ICU, 6304 patients were randomized to intensive glucose control with a target blood glucose range of 81 to 108 mg/dL or conventional glucose control with a target of 180 mg/dL or less. The primary endpoint was death from any cause within 90 days of randomization. A total of 829 patients (27.5%) in the intensive-control group and 751 (24.9%) in the conventional-control group died (odds ratio for intensive control 1.14; 95% confidence interval [CI] 1.02–1.28; P =.02). Severe hypoglycemia (blood glucose level ≤40 mg/dL) was reported in 206 of 3016 patients (6.8%) in the intensive-control group and 15 of 3014 (0.5%) in the conventional-control group ($P <$ .001). In this study, intensive glucose control increased mortality in ICU patients.

There is a marked difference in the design of the multicenter study versus the individual center studies, such as the routes of insulin administration, nutritional support, and glycemic targets in the control group. Some investigators have suggested that the target blood glucose control for ICU patients should be 140 to 180 mg/dL. This minimizes hypoglycemia, yet prevents excessive hyperglycemia.[126,129]

KEY POINTS

- Hyperglycemia is a common clinical issue in severely ill patients. It may represent previously unknown diabetes mellitus or a metabolic response to severe stress. Blood glucose levels that remain above 200 mg/dL are associated with increased morbidity and mortality. Maintaining blood glucose levels between 80 and 120 mg/dL with intensive insulin therapy increases the risk of severe hypoglycemia and does not reduce morbidity and mortality. The general consensus is that severe hyperglycemia in critically ill patients benefit if the hyperglycemia is treated to and maintained at a level of 140 to 180 mg/dL.

DRUGS THAT CAN CAUSE HYPERGLYCEMIA

Blood glucose is regulated by the balance between insulin secretion and insulin action. A drug that destroys β cells or blocks their insulin secretory function will cause hyperglycemia in any individual (Table 35.5). A drug that directly or indirectly increases insulin resistance can cause hyperglycemia only in individuals with β cells that have limited insulin secretory reserve (individuals with a predisposition to type 2 diabetes).

Drugs That Directly Adversely Affect β Cell Function

Pentamidine and pyriminil (Vacor) are substances that resemble streptozotocin and alloxan chemically. Pentamidine is an antiprotozoal agent that is used extensively to treat *Pneumocystis carinii* infection. Pyriminyl is a nitrosourea-derived rodenticide that can be accidentally or intentionally ingested by humans. These agents cause necrosis of β cells, leading initially to hyperinsulinemia and hypoglycemia, followed by permanent hyperglycemia and an insulin-dependent DM.[130-132] In a series of 128 patients with acquired immunodeficiency syndrome (AIDS) who were treated with pentamidine for *P. carinii* pneumonia, severe glucose homeostasis disorders developed in 48 patients (37.5%), hypoglycemia in seven, hypoglycemia and then diabetes in 18, and diabetes alone in 23.[131] Of the 41 patients in whom diabetes developed, 26 required insulin therapy. Risk factors for the development of dysglycemia include higher pentamidine doses, higher plasma creatinine, and more severe anoxia. Whereas most of the dysglycemic patients received parenteral pentamidine, six were treated exclusively with pentamidine aerosols.

Pyriminyl ingestion has been followed by severe insulinopenic DM in numerous instances.[132] Pyriminyl specifically inhibits the nicotinamide adenine dinucleotide–ubiquinone reductase activity of complex 1 in mammalian mitochondria.[133] This inhibition of mitochondrial respiration of NAD-linked substrates appears to be the mechanism by which pyrminyl destroys β cells and causes a form of insulin-dependent DM.

TABLE 35.5 Drugs That Interfere With Insulin Secretion

- Destroy β Cells
  - Pentamidine
  - Pyriminal
- Decrease Calcium Entry
  - Diazoxide–adenosine triphosphate–dependent potassium channel opener
  - Phenytoin (Dilantin)
- Decrease Potassium
  - Thiazides
  - Loop diuretics
- Activate Immune System Against β Cells
  - Immune checkpoint inhibitors
- Block Metabolism of β Cell or Insulin Action Cascade

  - Cyclosporin
  - Opiates
  - L-Asparaginase

Fluoroquinolones are a class of antimicrobial agents that can cause hypoglycemia or hyperglycemia. Although most of these complications occur in patients with known DM, they have also been observed in nondiabetic individuals. The fluoroquinolones that have been used clinically and for which glycemic complication data have been examined are gatifloxacin, levofloxacin, monifloxicin, and ciprofloxacin. In a review of patients who were being treated at hospitals in Ontario, Canada for dysglycemia occurring after antimicrobial therapy, 788 had hypoglycemia, and 470 had hyperglycemia during a 2-year period. Of those patients, gatifloxacin had an adjusted odds ratio for causing hypoglycemia of 4.3 and for causing hyperglycemia of 16.7 compared with macrolides or other nonfluoroquinolone antibiotics.[134] A retrospective analysis of a cohort of patients treated from October 1, 2000 through September 30, 2005 examined the crude incidence rates (cases per 1000 patients) for severe hypoglycemia and hyperglycemia in those treated with gatifloxacin (0.35 and 0.45), levofloxacin (0.19 and 0.18), ciprofloxacin (0.10 and 0.12), or azithromycin (0.07 and 0.10).[134,135] The odds ratios for hypoglycemia in diabetic patients compared with azithromycin were gatifloxacin 4.3, levofloxacin 2.1, and ciprofloxacin 1.1. The odds ratios for hyperglycemia were gatifloxicin 4.5, levofloxacin 1.8, and ciprofloxacin 1.0. In another study, dysglycemia (serum glucose above 200 mg/dL or below 50 mg/dL) was assessed within 72 hours of receiving fluroquinolones or ceftriaxone in 17,108 patients.[136] Dysglycemia rates were 1.01% for gatifloxacin, 0.93% for levofloxacin, 0.18% for ceftriaxone, and 0% for ciprofloxacin. Of the 101 patients with dysglycemia, hyperglycemia occurred in 92 and hypoglycemia in nine. The data show that the dysglycemic effect among individual fluoroquinolones varies greatly.

The fluoroquinolones can either acutely increase insulin secretion causing hypoglycemia or decrease insulin secretion causing hyperglycemia. *In vitro* studies with gatifloxacin have shown that it stimulates insulin release by blocking the Kir 6.2 subunit of the β cell adenosine triphosphate–dependent potassium (K_{ATP}) channel.[137] More chronic treatment with gatifloxicin inhibits insulin biosynthesis, thereby decreasing β cell insulin content and secretion. The predominant clinical effect will depend on the baseline status of the β cell at the time of fluoroquinolone treatment.[138]

Drugs That Inhibit Increases in β Cell Cytosolic Calcium

An increase in the β cell cytosolic calcium concentration is the major mechanism responsible for insulin secretion. Calcium ion entry into the β cell is controlled by several calcium ion channels. A voltage-dependent L-type calcium channel has its activity linked to a K_{ATP} channel. The K_{ATP} channel is closed by increases in plasma glucose. Drugs that keep the K_{ATP} channel open, such as diazoxide, block glucose-mediated insulin secretion and lead to hyperglycemia.[139]

Phenytoin (Dilantin) and other phenylhydantoins can interfere with sodium, potassium, and calcium ion transport. Dilantin administration has been reported to increase plasma glucose and decrease plasma insulin.[140,141] Several studies indicate that it interferes with calcium ion entry into the β cell by a process different from the K_{ATP} channel–related mechanism. Dilantin has been reported to cause hyperosmolar nonketotic hyperglycemia or new-onset DM. This complication occurs infrequently, and probably in individuals with some preceding genetic susceptibility. Currently used calcium channel blockers do not affect glucose metabolism. Confirmatory data come from a reanalysis of the data from the NAVIGATOR study in which calcium channel blockers were started in 1171 patients with IGT who were treated for a median of 5 years, and no increase in new-onset diabetes was noted.[142]

Drugs That Cause Potassium Depletion

Numerous studies have shown that diuretics can cause a deterioration in glucose tolerance in nondiabetic individuals and worsening of glycemic control in patients with type 2 diabetes.[143,144] The effect appears to be dose-related and is either absent or markedly reduced with low-dose diuretic therapy.[144,145] The Atherosclerosis Risk in Communities (ARIC) study compared 458 hypertensive patients treated with a thiazide diuretic for 6 years versus a control hypertensive cohort on no medications and found that the rates of development of new DM were no different.[145] In contrast, the Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT), which randomized 15,255 hypertensive patients to 12.5 to 25 mg/day of a diuretic, found that 11.6% of patients developed new-onset diabetes over 4 years of treatment.[14]. In contrast, the rate for patients randomized to a calcium channel blocker was 9.8%, and the rate for patients randomized to an angiotensin-converting enzyme inhibitor was 8.1%. In humans, diuretics appear to worsen glycemia primarily by inhibiting insulin secretion, although they also have a modest effect in increasing insulin resistance. Several studies have shown that the decreased insulin secretory response is attributed to intracellular potassium depletion and can be restored toward normal with potassium repletion.[147,148] In the ALLHAT study, 8.5% of the cohort randomized to the diuretic had a serum potassium less than 3.5 mEq/L at 4 years of treatment, but only 1.9% of the cohort randomized to the calcium channel blocker had this degree of hypokalemia.[146] Diabetogenic effects are seen with most diuretics. Therefore, if diuretics are used in diabetic or prediabetic patients to control blood pressure, doses should be restricted to that equivalent to 12.5 to 25.0 mg hydrochlorothiazide, and potassium supplements should be prescribed as needed.

Antiimmune and Cancer-Treatment Drugs

Cyclosporin and Tacrolimus. Cyclosporine and tacrolimus treatment for immunosuppression in renal transplant recipients is associated with an increased incidence of DM. Direct inhibitory effects of cyclosporine on β cells *in vitro* have been associated with decreased insulin secretion.[149] Although it is likely that cyclosporine has direct effects in causing deterioration in glucose tolerance in renal transplant patients, it is not possible to exclude a contributory role of the associated corticosteroid therapy.[150] The onset of DM in cyclosporine-treated patients occurs within the first several months of treatment and often requires insulin treatment. The reported incidence of DM and glucose intolerance in cyclosporine-treated transplant patients ranges from 13% to 47%.

Tacrolimus has been associated with development of DM and, in a few cases, with DKA.[151] During a 3-year period, 7.1% of patients treated with tacrolimus for interstitial pneumonia secondary to polymyositis and dermatomyositis developed newly diagnosed DM. Tacrolimus-induced DKA has been reported in 15 patients after transplantation. Evidence suggests that tacrolimus suppresses insulin secretion by inhibiting the transcription of the insulin gene because of association between tacrolimus and the FK506-binding protein 12. The diabetogenic effect of tacrolimus is dos- dependent and reversible.

mTOR Inhibitors. mTOR inhibitors are anticancer treatments, and hyperglycemia has been reported in 12% to 50% and hyperlipidemia in 7% to 73% of patients in phase III trials of everolimus and temsirolimus.[152] Severe hyperglycemia (>13.9 mmol/L) is less frequent (4%–12%). DKA has not been reported. In a metaanalysis of 24 clinical trials of everolimus or temsirolimus in 4261 patients with various types of tumors, hyperglycemia and severe hyperglycemia were 2.95 and 5.25 more likely with mTOR inhibitor treatments than with control treatment.[153] A median time of 58 days to maximal hyperglycemia was noted in 75 patients treated by everolimus or temsirolimus. TOR inhibition by rapamycin leads to a 33% reduction in glucose-induced insulin secretion and a 50% reduction in β cell mass by increased apoptosis. Rapamycin also reduces insulin sensitivity at the level of the liver and adipose tissue. The development of hyperglycemia and hyperlipidemia during therapy requires standard treatments and often continuation of the mTOR inhibitor, albeit at a lower dose.

Immune Checkpoint Inhibitors. Immune checkpoint inhibitors (ICPIs) are immunotherapy agents that work primarily by using the immune system to target and eradicate cancer cells. Currently, ICPIs include three drug classes of monoclonal antibodies named after their targets: anti–cytotoxic T-lymphocyte 4 antigen antibody (anti-CTLA-4 Ab), programmed cell death-1 inhibitors (PD-1 inhibitors), and programmed cell death ligand-1 inhibitors (PDL-1 inhibitors). Examples of drugs in these categories are ipilimumab and tremelimumab (anti-CTLA-4 Ab), nivolumab and pembrolizumab (PD-1 inhibitors), and atezolizumab and durvalumab (PDL-1 inhibitors). ICPIs have undesired off-target effects, collectively referred to as immune-related adverse events (irAEs). Overall, irAEs are seen in approximately 50% to 60% of patients treated with ICPIs. Endocrinopathies reported in clinical trials include lymphocytic hypophysitis (0%–17%), Grave disease and thyroiditis (6%–20%), and, less commonly, primary adrenal insufficiency and type 1 diabetes. PD-1 inhibitor treatments (nivolumab or pembrolizumab) have caused hyperglycemia within days to weeks after the first dose.[154,155] These patients may even present with DKA.[155] Of five hyperglycemic PD-1 inhibitor–treated patients, three had DKA, with undetectable C-peptide levels and positive glutamic acid decarboxylase 65 antibodies resembling the findings of classic type 1 diabetes.

Tyrosine Kinase Inhibitors. Tyrosine kinase activates a family of enzymes involved in cell proliferation, cellular metabolism, and angiogenesis. Blocking these pathways with tyrosine kinase inhibitors (TKIs) is a key component for antiangiogenic therapies. Examples of these drugs, which have been used to treat a variety of cancers, include sorafenib, sunitinib, pazopanib, axitinib, vandetanib, lenvatinib, erlotinib, gefitinib, and regorafenib. Tyrosine kinase activation is a vital component for activation of the insulin signaling cascade, and it might be expected that TKI would increase insulin resistance. However, in patients with preexisting diabetes receiving TKIs, mean blood glucose concentrations declined by 9 to 53 mg/dL compared with normal controls. In one study involving TKI treatment, eight of the 17 patients with diabetes were able to discontinue their glucose-lowering medications, including insulin. Although the mechanism of glucose lowering is not understood, it appears that TKI treatment increases β cell mass and function.

Phosphoinositide 3-Kinase Inhibitors. Phosphoinositide 3-kinase (PI3K) activation mediates intracellular insulin action, as well as that of other growth regulators like epidermal growth factors, IGFs, and vascular endothelial growth factors, making it a key regulator of cell cycle checkpoints affecting apoptosis, proliferation, and growth. There are three classes of PI3K pathway inhibitors: pan-PI3K inhibitors, isoform-specific PI3K inhibitors, and pan–protein kinase B (Akt) inhibitors. Alterations of the PI3K/Akt pathways are common in breast and other cancers. Blocking PI3K interferes with insulin signaling and results in insulin resistance.[156,157] There are many PI3K inhibitor drugs, each of which is specific for its class of inhibitor. Hyperglycemia, which typically appears within the first two cycles of treatment, has been reported in the range of 51% to 65% of patients taking alpelisib with endocrine therapy in clinical trials.[156] Hyperosmolar and ketoacidosis states are extremely rare but may occur in patients with preexisting diabetes. Once hyperglycemia is detected, mild increases in FPG (160 mg/dL) do not require dose modifications of the PI3K inhibitor, but rather initiating metformin 500 mg once daily and increasing each dose by an additional 500 mg as needed up to a maximum dose of 2000 mg daily. For FPGs between 160 and 250 mg/dL, the PI3K pathway inhibitor can be maintained at the same dose, and the metformin dose increased. If the metformin dose has been maximized, and the FPG has not improved, an insulin-sensitizing agent should be added. If hyperglycemia does not improve within 21 days to FPG less than 160 mg/dL, the patient should restart alpelisib at a lower dose. In patients who develop FPG greater than 250 mg/dL, treatment with alpelisib should be interrupted for 1 to 2 days until blood glucose improves.

L-Asparaginase. L-asparaginase is a chemotherapeutic agent for management of acute lymphoblastic leukemia and other hematopoietic malignancies. The antineoplastic activity results from cleavage of L-asparagine to aspartic acid and ammonia and depletion of the L-asparagine circulating pool, which in turn inhibits protein synthesis, causes cell cycle arrest in the G1-phase, and ultimately causes apoptosis in susceptible leukemic cells. Unlike normal cells, leukemic cells and other cancer cells have little or no asparagine synthetase. L-asparaginase treatment is associated with reduced insulin synthesis and secretion and possibly a decrease in the expression of insulin receptors.[158,159] L-asparaginase–associated hyperglycemia has been reported in 4% to 20% of pediatric patients receiving *Escherichia coli* L-asparaginase and in 4% to 17% of patients receiving *Erwinia chrysanthemi* asparaginase.[158,159] Hyperglycemia is more common during phases of therapy when L-asparaginase and corticosteroids are administered together and in relatively higher doses. The L-asparaginase preparation and the type of corticosteroid (prednisone or dexamethasone) used in treatment do not seem to influence the risk of hyperglycemia. Hyperglycemia tends to resolve within 12 days after the last dose. More severe cases and DKA can occur in patients with other risk factors for DM. Insulin therapy may be required in severe cases; however, L-asparaginase therapy can continue if the patient shows glucose levels of 200 mg/dL or less with insulin treatment.

KEY POINTS

- Drugs that are toxic to β cells and cause their deaths, interfere with the insulin secretory processes in the β cell, or block the intracellular action of insulin cause hyperglycemia. If they cause destruction of β cells, such as occurs with pentamidine or fluroquinolones, the clinical picture will be initial hypoglycemia followed later by permanent diabetes mellitus. Checkpoint inhibitors cause autoimmune destruction of β cells and a type 1 diabetes–like syndrome. If drugs interfere with insulin secretion by blocking calcium entry or potassium flux in the β cell, the hyperglycemia is reversible by discontinuing the drug or adding a drug to treat the hyperglycemia. The same is true for drugs that block the intracellular insulin action pathway (tacrolimus, mTOR inhibitors, phosphoinostide 3-kinase inhibitors, L-asparaginase).

Mechanisms Unknown. β-adrenergic antagonists have been shown to worsen glycemic control in type 2 diabetic patients and to impair glucose tolerance or even precipitate type 2 diabetes in nondiabetic patients.[160] A 6-year follow-up of hypertensive patients treated with β-adrenergic receptor antagonists in the ARIC study showed a 28% higher risk for development of diabetes than that in hypertensive patients not undergoing drug therapy.[145] The deleterious effect of β-adrenergic blockade on glucose tolerance is worse with nonspecific β-adrenergic receptor blockade than with specific β_2-adrenergic antagonists.[160,161] Combination therapy with β-adrenergic antagonists and diuretics has an additive effect of worsening glucose tolerance. Among 19,257 hypertensive patients randomized in the Anglo-Scandinavian Cardiac Outcome Trial Blood Pressure Lowering Arm, baseline FPG greater than 5 mmol/L, BMI, and the use of atenolol were among the highest risk factors for the development of new-onset DM.[162] β-adrenergic antagonists impair glucose tolerance and worsen hyperglycemia by blocking nutrient-mediated insulin secretion.[163] β_2-adrenergic receptor activation stimulates, and β_2-adrenergic receptor blockade inhibits, insulin secretion. Drugs with both α- and β-adrenergic receptor antagonist activity have no effect or may slightly improve glucose metabolism.

Drugs That Cause Insulin Resistance

Drugs that increase insulin resistance will not affect glucose metabolism in individuals with normal β cell function. However, when administered to individuals with limited β cell reserve, they will cause glucose intolerance or overt DM. Agents that cause an increase in body weight, and particularly those associated with an increase in central obesity, will cause insulin resistance. Drugs or hormones that elevate plasma free fatty acid levels will lead to insulin resistance. Counterregulatory hormones or drugs that raise circulating levels of counterregulatory hormones will cause impairment of insulin action. The most used agents that can increase insulin resistance are glucocorticoids, estrogens, progestogens, and nicotinic acid. Hyperglycemia associated with glucocorticoid therapy has been discussed in the section on Cushing syndrome.

Oral Contraceptives and Sex Hormones

Older studies investigating the effects of oral contraceptives, estrogens, and progestogens showed that deterioration of glucose tolerance and development of type 2 diabetes were occasional complications of long-term therapy.[164] Most studies attributed the diabetogenic effects of these steroids to an increase in insulin resistance. Recent studies with lower-dose natural estrogens (ethinyl-estradiol lower than 35 mcg) combined with progestogens indicate that these regimens produce little or no increase in glucose intolerance, even though they may cause a small increase in insulin resistance.[165] Progesterone-only contraceptives have weak effects on glucose and lipid metabolism that vary depending on the specific molecules employed.

Nicotinic Acid

Nicotinic acid is used extensively to treat mixed hyperlipidemias and has been shown to decrease morbidity and mortality from cardiovascular disease. Short-term administration of nicotinic acid reduces plasma free fatty acid levels by 30% to 40%, but as the drug effect wears off, the plasma free fatty acids rebound to 50% to 100% above baseline concentrations. Long-term administration of nicotinic acid at 1 to 4.5 g/day causes severe insulin resistance, presumably as the result of elevated plasma free fatty acid levels. Normal individuals have a compensatory rise in insulin secretion, and glucose tolerance remains normal. In individuals with diminished insulin secretory reserve, nicotinic acid causes glucose intolerance and type 2 diabetes.[166] In type 2 diabetic patients, nicotinic acid administration results in marked deterioration in glycemic control.[167,168] Newer extended-release niacin preparations at doses of 1000 and 1500 mg/day have been shown to be very effective in raising plasma high-density lipoprotein (HDL) cholesterol and lowering plasma triglyceride levels with markedly reduced flushing and hepatotoxicity. The Assessment of Diabetes Control and Evaluation of the Efficacy of Niaspan Trial, which evaluated the effect of extended-release niacin in type 2 diabetic patients, showed no effect on glycemic control at 1000 mg/day and only a minor increase in HbA1c (+0.29%) over 16 weeks of therapy.[168] These data indicate that the advantages of extended-release niacin in improving diabetic dyslipidemia far outweigh any detrimental effects on glycemic control.

Two large clinical trials have studied the effects of adding extended-release niacin to statin therapy to increase cardiovascular benefits in high-risk individuals. The AIM-HIGH study failed to show an incremental cardiovascular benefit when extended-release niacin was administered to patients with atherosclerotic heart disease and low-density lipoprotein (LDL) cholesterol levels less than 1.81 mmol/L. Patients who had DM had a modest increase in their hyperglycemia.[169] Extended-release niacin caused an increase in those with normal glucose tolerance progressing to IGT (58.6% vs. 41.5% of controls) but no increase in new-onset DM.[168] In the Heart Protection Study 2-Treatment of HDL to Reduce the Incidence of Vascular Events study, niacin–laropiprant, as compared with placebo, was associated with a 55% proportional increase in disturbances in diabetes control(11.1% vs. 7.5%, $P < .001$) most of which led to hospitalization.[170] In an analysis of the 17,374 participants who did not have diabetes at the time of randomization, assignment to niacin–laropiprant, as compared with assignment to placebo, was associated with a 32% proportional increase in the diagnosis of diabetes (5.7% vs. 4.3%, $P < 0.001$) [170].

LIPID-LOWERING AGENTS AND NEW-ONSET DIABETES MELLITUS

Statins

Multiple clinical studies show that statin therapy is associated with an increase in the development of type 2 diabetes and a worsening of glycemic control in patients who have type 2 diabetes. In a collaborative metaanalysis of 13 randomized statin trials involving 91,140 participants, 4278 developed diabetes during a mean of 4 years.[171] Of the patients who developed diabetes, 2236 had been assigned to statin therapy and 2032 to control treatment. Statin therapy was associated with a 9% increase in diabetes. Treatment of 255 individuals with statin therapy for 4 years resulted in one extra new case of diabetes.

The benefits of statin therapy in lowering cardiovascular events and death have been assessed in patients at high to low risk for cardiovascular disease. Overall statin therapy shows that, for each 1-mmol/L decrease in LDL cholesterol, there is a 10% proportional reduction in all-cause mortality, a 20% reduction in deaths from coronary heart disease, and a 22% reduction in major vascular events. Even in individuals with a 5-year risk of major vascular events lower than 10%, each 1-mmol/L reduction in LDL cholesterol produces an absolute reduction of major vascular events of approximately 11/1000 over 5 years.[172]

A detailed analysis of the cardiovascular benefits and diabetes risks of statin therapy in primary prevention was carried out for the 17,603 participants in the JUPITER trial.[173] Patients were classified into those with one or more major risk factors for diabetes at baseline (metabolic syndrome, impaired fasting glucose, BMI ≥30 kg/m^2, or HbA1c ≥6%; n = 11,508) and those with no major risk factors (n = 6095). In individuals with one or more major risk factors for diabetes at baseline, statin therapy was associated with a 39% reduction in the cardiovascular endpoint, a 36% reduction in venous thromboembolism, a 17% reduction in total mortality, and a 28% increase in DM. In trial participants with no major diabetes risk factors, statin treatment was associated with a 52% reduction in the primary cardiovascular endpoint, a 53% reduction in venous thromboembolism, a 22% reduction in all-cause mortality, and no increase in DM.

All data indicate that the benefits of statin therapy in reducing cardiovascular events far exceed the risk for statin-induced acceleration of the onset of type 2 diabetes in both primary prevention and secondary treatment.[174,175]

Proprotein Convertase Subtilisin/Kexin Type 9 Inhibitors

The proprotein convertase subtilisin/kexin type 9 (PCSK9) modulates cholesterol homeostasis by increasing the endosomal and lysosomal cleavage of hepatic LDL receptor, which increases serum LDL cholesterol levels. Inhibition of PCSK9 dramatically lowers circulating LDL cholesterol. Several monoclonal antibodies that inhibit PSCK9 are available and have been shown to lower LDL cholesterol. Evolocumab, when added to patients on statin therapy with a median LDL cholesterol of 92 mg/dL, decreased it to a median of 30 mg/dL (59%).

Multiple studies and metaanalyses show that PCSK9 inhibitors do not alter glucose metabolism and do not increase new-onset DM. These data prove that statin-induced increases in new-onset DM are not related to LDL cholesterol lowering.[176]

Cholesterol Ester Transfer Protein Inhibitors

A metaanalysis of four cholesterol ester transfer protein (CETP) inhibitor trials involving a total of 73,479 patients, including 960 newly diagnosed cases of diabetes in the CETP inhibitor group versus 1086 in the placebo group, showed a significant (12%) reduction in the incidence of DM (odds ratio 0.88; 95% CI: 0.81–0.96; P = .005).[177] A statistically nonsignificant trend (Z = –1.13, P = .26) was noted for an increase in HDL cholesterol and the inhibition of CETP. In contrast to the cholesterol-lowering agents, CETP inhibitors reduced the incidence of new-onset DM. The role of the increase in HDL cholesterol in the improvement in glucose metabolism is unclear.

KEY POINTS

- Nicotinamide causes insulin resistance and increases hyperglycemia and the prevalence of new-onset diabetes mellitus (DM) in patients with reduced insulin secretory capacity. Statin therapy is associated with an increase in new-onset DM or worsening of glycemia in patients with DM. The mechanism by which statins cause deterioration of glucose metabolism is multifactorial and includes an increase in insulin resistance, as well as modification of β cell insulin secretion. Individuals at risk for statin-induced DM are those who previously had known risk factors for DM. Analyses have demonstrated that the cardiovascular benefits of statins greatly exceed the detrimental effects of the associated new-onset DM. Proprotein convertase subtilisin/kexin type 9 inhibitor treatment of hypercholesterolemia has no increased risk of DM, indicating that the statin-induced DM is independent of its cholesterol-lowering activity. Clinical trials have shown that inhibitors of cholesterol ester transfer protein decrease the development of new-onset DM.

ACQUIRED IMMUNODEFICIENCY SYNDROME AND ANTIRETROVIRAL DRUGS

Human immunodeficiency virus (HIV) has infected 76 million people, 33 million of whom have died since the epidemic began in the 1980s. Initially, AIDS was a rapidly progressive disease culminating in death within several years. Antiretroviral drugs (protease inhibitors [PIs], nucleoside reverse-transcriptase inhibitors [NRTIs], nonnucleotide reverse-transcriptase inhibitors [NNRTIs], and, more recently, integrase inhibitors) were developed that, when administered in various combinations, suppress viral replication to levels that are undetectable in the peripheral circulation and improve immune function.[178] Consequently, AIDS has gone from being an acute fatal disease to a chronic illness that, with proper management, can be associated with a life expectancy several years shy of normal. Globally, 38 million people (an estimated 0.7% of those aged 15–49 years worldwide) were living with HIV at the end of 2019. The burden of the epidemic continues to vary considerably between countries and regions. Africa remains most severely affected, with nearly 1 in every 25 adults in this region living with AIDS.

Antiretroviral drugs (PIs, NRTIs, and NNRTIs) are associated with the development of lipodystrophies, dyslipidemia, and glucose intolerance.[178] HIV/AIDS itself is associated with increased plasma triglycerides and decreased plasma total, LDL, and HDL cholesterol levels.[179] The PIs indinavir, nelfinavir, ritonavir, and saquinavir were early antiretroviral agents, and their use was reported to cause an unusual lipodystrophy. The main clinical features of this lipodystrophy are peripheral lipoatrophy of the face, limbs, and buttocks and central fat accumulation, including over the dorsocervical spine.[180] Patients with HIV who were newly exposed to antiretroviral therapy (ART) were found to have prevalence of HIV lipodystrophy between 20% and 35% after 12 to 18 months of therapy.[180] In addition to lipodystrophy, ART has been associated with the development of new hyperglycemia; hypercholesterolemia including elevated LDL cholesterol, very low-density lipoprotein, and ApoB levels; low HDL cholesterol; and hypertriglyceridemia.[180-185] Newer antiretroviral agents cause less peripheral lipodystrophy but still increase central fat, insulin resistance, and the metabolic syndrome. The dyslipidemia occurs within 3 months of initiation of ART therapy and plateaus within 6 to 9 months.[179] The prevalence of new-onset hyperglycemia with ART has been reported to vary from 1% to approximately 8%. In the Multicenter AIDS Cohort Study, the incidence of type 2 DM (14%) was more than four times greater in HIV-infected men receiving ART than in HIV-seronegative controls.[185] Tsiodras and coworkers presented data from a 5-year cohort study of 221 HIV-infected patients treated with PIs showing that the cumulative incidences of new-onset hyperglycemia, hypercholesterolemia, hypertriglyceridemia, and lipodystrophy were 5%, 24%, 19%, and 13%, respectively.[186] The prevalence and incidence of hyperglycemia in HIV patients treated with ART are influenced by concomitant hepatitis C virus infection. Retrospective analysis of a cohort of 1230 persons on their first ART regimen revealed a prevalence of hyperglycemia in hepatitis C–coinfected patients of 5.9% versus 3.3% in uninfected patients.[187] The mechanism responsible for the protease-induced hyperglycemia appears to be the development of peripheral insulin resistance in skeletal muscle and adipose tissue through inhibition of GLUT-4 translocation.[188] Pancreatic β cell function is also impaired, so it cannot compensate for the insulin resistance.[188,189] The thymidine analog NRTIs induce mitochondrial dysfunction.[178] At the present time, it is unclear how ART causes lipodystrophy and other related metabolic side effects. The data indicate that ART-mediated metabolic side effects are not related to virologic suppression, CD4 cell count, or changes in weight. Dube and colleagues reported seven new cases of diabetes occurring in a population of 1050 patients treated with PIs over a 9-month period, for a rate of less than 1%.[182] Two patients were treated successfully with insulin and two with sulfonylureas. Two patients had resolution of their hyperglycemia by stopping indinavir therapy. Kilby and Tabereaux determined the frequency of severe hyperglycemia in a university clinic for HIV-1–infected patients and found a prevalence of less than 2%.[183] Preexisting diabetes was present in 12 of 1392 adults, and new cases of hyperglycemia occurred in 13 of these 1392 adults.[184] Most of the incident cases could be attributed to megestrol or corticosteroid treatment. All HIV ART series show a much lower prevalence of hyperglycemia than of dyslipidemia or lipodystrophy.

The use of HbA1c measurements for the diagnosis or for following treatment for type 2 diabetes is confounded. In one study, HbA1c underestimated average blood glucose by 1.7 mmol/L (equivalent to 1% HbA1c).[188] This was not confirmed in a study of HIV-infected women.[178,190] Factors associated with this discordance between actual and predicted HbA1c include higher mean corpuscular volume, NRTI use, and abacivir use. Additional studies are required to clarify the validity of HbA1c measurements in HIV/AIDS patients on ART.

The therapy of type 2 diabetes in HIV/AIDS patients on ART must consider drug interactions. Antidiabetic agents that are metabolized by the cytochrome P-450 3A4, such as sitagliptin, should be avoided, as their use will interfere with the metabolism of some of the antiretroviral agents such as ritonavir.[178]

ATYPICAL ANTIPSYCHOTIC AGENTS

The atypical antipsychotic drugs represent several chemical classes of drugs that have been shown to have beneficial effects in patients with schizophrenia and manic-depressive disorder. They differ from older agents in that they are associated with significantly fewer extrapyramidal side effects and provide superior beneficial effects. They bind to a variety of serotonin, dopamine, and histamine receptors.[191] Atypical antipsychotic drugs include clozapine, olanzapine, risperidone, quetiapine, ziprasidone, aripiprazole, and amisulpride.

Shortly after their introduction for the treatment of schizophrenia, case reports appeared documenting the development of new cases of DM during therapy with clozapine and olanzapine.[192] Because clozapine and olanzapine cause considerable weight gain,[193] the question was posed as to whether the weight gain might be responsible for the development of diabetes. It also was speculated that schizophrenia itself is associated with an increased prevalence of type 2 diabetes. A metaanalysis of healthy volunteers who received atypical antipsychotics during clinical trials evaluated their effects on insulin sensitivity with or without weight gain and with treatment length. The data showed that atypical antipsychotics decrease insulin sensitivity (standardized mean difference = −0.437, $P < .001$).[194] It was found that decreases in insulin sensitivity were potentially dependent on treatment length and not on weight gain. Decreases in insulin sensitivity occurred in less than 13 days, whereas weight gain occurred in studies that lasted 14 days and longer (maximum 28 days). These findings indicated that atypical antipsychotics cause insulin resistance and weight gain directly, independent of psychiatric disease, and may be associated with length of treatment.[194]

Subsequently, numerous reports, large healthcare databases, and reviews have appeared in the literature citing new cases of diabetes and hypertriglyceridemia as complications of therapy with clozapine and olanzapine.[191,195] Clozapine and olanzapine treatment are associated with a mean weight gain of approximately 10 kg over the first year of treatment. Risperidone and quetiapine cause weight gain of approximately 2 to 3 kg. In contrast, ziprasidone and aripiprazole treatment cause minor amounts of weight gain (0.5–1.0 kg over 1 year). The amount of weight gain caused by olanzapine and clozapine varies considerably among patients. In a US study of 474 adults treated for 24 months, 23.2% gained no weight, 47.5% gained up to 10 kg, 20.8% gained between 10 and 20 kg, and 8.6% gained more than 20 kg.[195] Clozapine and olanzapine treatment have been shown in several studies to cause insulin resistance.[196] Ziprasidone and aripiprazole did not appear to cause insulin resistance. The data on risperidone and quetiapine were not enough to confirm, but these agents appeared to have little effect.

In one long-term study of clozapine treatment of patients with schizophrenia, the 5-year cumulative prevalence of DM was 36%, and in another with a mean follow-up of 12.3 years, the rate of newly detected diabetes was 22.3%.[197,198] Published reports and Med-Watch data from the US Food and Drug Administration (FDA) have been reviewed by Koller et al.,[199,200] who found new-onset cases of diabetes in 188 patients on olanzapine, 132 on risperidone, and 242 on clozapine. Approximately 40% of those cases presented as DKA. Some 70% of patients developed diabetes within 6 months of starting olanzapine. When olanzapine was discontinued, 76% of patients exhibited improvement or remission of their diabetes. Among 10 patients who had had a remission and were rechallenged with olanzapine, diabetes recurred in 80%. Although the development of new-onset diabetes was frequently associated with significant weight gain, this was not always the case. In a 9-day treatment of normal individuals, olanzapine was shown to increase insulin resistance and increase meal-mediated secretion of insulin, GLP-1, and glucagon in the absence of weight gain.[201] In contrast, aripiprazole increased insulin resistance but had no effect on postprandial hormone secretions. Ziprasidone and aripiprazole appear to have significantly fewer metabolic side effects.

The mechanism by which atypical antipsychotics cause diabetes is unclear. A literature search and metaanalysis published in 2017 [202] identified 83 psychiatric patients who presented with DKA while taking atypical antipsychotic drugs: olanzapine 32, clozapine 19, risperidone nine, quetiapine eight, aripiprazole six, and two atypical antipsychotics nine. The DKA patients were more likely to be male and younger, and a greater proportion of them were not obese, compared with patients who develop type 2 diabetes. The development of DKA in so many patients taking atypical antipsychotics indicates that these drugs significantly impair β cell insulin secretory function, as well as impairing insulin action.

In a metaanalysis involving 23,799 patients with schizophrenia and related diseases, metabolic syndrome was found in 51.9% of patients on clozapine and 28.2% of those on olanzapine.[203] Nineteen percent of the pooled patients had hyperglycemia (plasma glucose >100 mg/dL), and 39.3% had hypertriglyceridemia. In an analysis of a database of 345,937 patients treated with an antipsychotic drug and 1,426,488 unexposed controls, the risk for developing DM was 1.3-fold greater with second-generation antipsychotic drugs compared with treatment with first-generation drugs.[204]

In addition to diabetes, clozapine and olanzapine cause hypertriglyceridemia in many patients.

Because no randomized, controlled comparative studies have investigated the effects of the different atypical antipsychotic agents on the development of diabetes, current conclusions must be viewed with some reservations. The FDA has taken the position that all atypical antipsychotic agents should be viewed as creating a risk for new-onset diabetes. A joint consensus conference sponsored by the American Diabetes Association and the American Psychiatric Society came to a different conclusion.[205] Their conclusions can be summarized as follows: the prevalence of the three adverse conditions (obesity, diabetes, dyslipidemia) differs among the second-generation antipsychotics:

1. Clozapine and olanzapine are associated with the greatest weight gain and with diabetes and dyslipidemia.
2. Risperidone and quetiapine appear to have intermediate effects.

3. Aripiprazole and ziprasidone are associated with little or no significant weight gain, diabetes, or dyslipidemia but have less usage exposure.

The consensus panel made the following recommendations:

1. If a patient gains 5% of his or her initial weight during therapy, one should consider switching the specific antipsychotic agent.
2. For patients who develop worsening glycemia or dyslipidemia while on antipsychotic therapy, the panel recommends considering switching to an agent that has not been associated with weight gain or diabetes.

Unfortunately, little progress has been made in further defining the risks or the mechanisms of the metabolic abnormalities associated with the different atypical antipsychotics. A large, randomized, initially double-blind, controlled clinical trial comparing the effectiveness and safety of olanzapine, risperidone, quetiapine (a first-generation antipsychotic), perphenazine, and ziprasidone was carried out in 1493 patients from January 2001 through December 2004 under the auspices of the National Institute of Mental Health; it was called the Clinical Antipsychotic Trial of Intervention Effectiveness.[206] The first phase was projected to last 18 months; however, 74.5% of patients discontinued their medications before the end of the first phase. The results suggested that olanzapine was somewhat more effective in controlling the symptoms of schizophrenia; however, its use was associated with a mean weight gain of 9.4 kg, an increase in plasma glucose of 15 mg/dL, an increase in HbA1c of 0.41%, an increase in plasma cholesterol of 9.7 mg/dL, and an increase in plasma triglyceride of 42.9 mg/dL. Quetiapine and risperidone showed minimal increases compared with the first-generation agent, and ziprasidone caused no weight, glycemic, or lipid effects. Because of the high rate of discontinuation of initial medications, the validity of the data must be interpreted with caution. Scheen and De Hert performed a prospective, open, nonrandomized study comparing the metabolic effects of six atypical antipsychotics in 238 schizophrenic patients who underwent a fasting analysis and an OGTT at baseline and after 3 months of treatment.[207] Weight gain, glucose alterations, incidence of new diabetes, and development of metabolic syndrome were greatest with clozapine, followed by olanzapine, then quetiapine, risperidone, and amisulpride. Aripiprazole was not associated with weight gain, improved glucose tolerance, and reduced the occurrence of metabolic syndrome. Thus, the newer data, although not ideal, confirm the conclusions derived from previous reports.

Another 6-month multicenter, randomized, double-blind trial involving 59 patients attempted to determine the mechanisms by which olanzapine and risperidone cause their metabolic effects.[208] Patients had baseline anthropomorphic measurements and measurement of total body fat by dual-energy x-ray absorptiometry analysis, visceral fat by abdominal computed tomography, and insulin sensitivity and disposition index by frequently sampled intravenous glucose tolerance using the Bergman technique. Patients were randomized to olanzapine or risperidone, and the studies were repeated at 6 months. Both drugs induced weight gain and increased total body and visceral fat. Insulin sensitivity did not deteriorate, nor was a significant change noted in disposition index (a composite measure of changes in insulin sensitivity and insulin secretion). A subset analysis of Black American and Hispanic subjects suggested that they had greater susceptibility to the detrimental effects of olanzapine in increasing insulin resistance and decreasing pancreatic compensation to insulin resistance.

It seems fair to conclude that weight gain plays some role in the development of the metabolic effects of atypical antipsychotic agents. However, other unknown factors also contribute, and the factors contributing to β cell failure are still unknown. Clozapine and olanzapine are the worst offenders in causing metabolic side effects, quetiapine and risperidone cause significantly fewer metabolic alterations, and ziprasidone and aripiprazole seem to produce minimal metabolic side effects. Metformin has been suggested as a treatment option for atypical antipsychotic–induced DM; however, many of these patients will require insulin. Vitamin D has been suggested as an agent that may prevent the atypical antipsychotic–mediated hyperglycemia.[209]

KEY POINTS

- Both the antiretroviral agents developed to treat acquired immunodeficiency syndrome and the atypical antipsychotic drugs used to treat schizophrenia have been shown to cause dramatic disturbances in lipid and glucose metabolism. The antiretroviral agents cause an unusual lipodystrophy, hypertriglyceridemia, and new-onset diabetes mellitus (DM). The lipid and adipose tissue effects are most prevalent and severe, whereas the effects on glucose metabolism are more modest and variable. The reported increase in DM varies from 1% to as high as 12%. The mechanism responsible for the metabolic effects are unclear, but the drugs do cause an increase in insulin resistance. The metabolic effects of the atypical antipsychotics clozapine and olanzapine are characterized by striking weight gain, a prevalence of DM of 22%–36%, and a significant incidence of diabetic ketoacidosis. Although the marked weight gain causes insulin resistance, which would increase DM because of limited insulin reserve, the development of ketoacidosis in many treated patients indicate some impairment of β cell function.

CONCLUSION

Hyperglycemia is a frequent complication of many diseases and medications that interfere with either insulin secretion or insulin action. Hyperglycemia decreases physiologic responses, such that defense against infections, metabolic adaptation, and protein synthesis are impaired. The consequences are that hyperglycemia increases the complications of the associated illness or the therapy and, in many instances, decreases survival. The recognition of the potential for hyperglycemia should alert the healthcare provider to undertake preventive measures or, in the case of advent of hyperglycemia, immediate and effective therapy.

β Cell Glucose Toxicity and Oxidative Stress

Anath Shalev, Jamie S. Harmon and R. Paul Robertson

OUTLINE

Introduction, 632
Normal Carbohydrate Biochemistry and Abnormal Glucose Metabolism Secondary to Chronic Hyperglycemia With Excess Generation of Reactive Oxygen Species, 632
General Overview of Free Radical Biology and Antioxidants as Defense Mechanisms Against Elevated Cellular Generation of Reactive Oxygen Species, 632
Evaluation of Oxidative Stress and Defective Endogenous Antioxidant Response in β Cells From the Points of View of the Glutathione and Thioredoxin Pathways, 634
Brief Overview of the Contributions of Oxidative Stress to Secondary Complications of Diabetes, 637

INTRODUCTION

This chapter considers mechanisms by which chronic elevations of blood glucose over an extended period can contribute to the deterioration of β cell function observed in type 2 diabetes mellitus (T2DM) and to the secondary complications that accompany both type 1 diabetes mellitus (T1DM) and T2DM. At the center of this information is the hypothesis that chronically elevated cellular levels of glucose and glucose-derived reactive oxygen species (ROS) cause tissue damage, hence the term *glucose toxicity*. This hypothesis recognizes that physiologic levels of ROS are favorable for many biochemical processes but emphasizes that prolonged elevations of ROS cause tissue damage. This hypothesis allows for possible adverse contributions from fatty acids and other lipids, which gives rise to the term *lipotoxicity*. Often the combined term, *glucolipotoxicty,* is used in the scientific literature.[1,2] This chapter will emphasize an evaluation of two important endogenous antioxidant systems designed to regulate the level of ROS in β cells to provide critical defense mechanisms against oxidative stress, the glutathione (Gsh)and thioredoxin (Trx) pathways.

KEY POINTS

- This chapter will emphasize an evaluation of two important endogenous antioxidant systems designed to regulate the level of reactive oxygen species in β cells to provide critical defense mechanisms against oxidative stress, the glutathione and thioredoxin pathways.

NORMAL CARBOHYDRATE BIOCHEMISTRY AND ABNORMAL GLUCOSE METABOLISM SECONDARY TO CHRONIC HYPERGLYCEMIA WITH EXCESS GENERATION OF REACTIVE OXYGEN SPECIES

The preferred biochemical pathway for glucose metabolism is glycolysis and oxidative phosphorylation. High glucose concentrations increase the mitochondrial proton gradient because of overproduction of electron donors by the tricarboxylic acid cycle. Excess glucose increases production of mitochondrial superoxide, a ROS. With prolonged exposure to high glucose levels, oxidative phosphorylation is swamped, and glucose is diverted to other pathways (Fig. 36.1) that independently increase ROS levels.[3] This creates a toxic state for the islet, because excess ROS has adverse consequences for insulin gene expression, insulin content, and insulin secretion.[4-8] The defect in insulin gene expression is caused by the loss of at least two essential transcription factors, Pdx-1 and MafA (Fig. 36.2 and 36.3). The defect in Pdx-1 synthesis is posttranscriptional,[9] whereas the defect in MafA is posttranslational.[10]

The clinical state of diabetes mellitus is often accompanied by elevated levels of blood cholesterol, triglyceride, and free fatty acids, which gave rise to the concept of *lipotoxicity*.[11,12] The adverse effects of high glucose levels converge with independent adverse consequences of lipotoxicity, both of which can cause increased β cell apoptosis.[1,13] Prolonged exposure of β cells to fatty acids has been reported to inhibit insulin gene expression.[11,12] A prominent hypothesis is that in the presence of high glucose and fatty acid concentrations there is an accumulation of cytosolic citrate, the precursor of malonyl-CoA, which inhibits carnitine palmitoyltransferase-1 synthesis. This enzyme is responsible for fatty acid transport into the mitochondrion, and in its absence free fatty acids are shunted toward esterification pathways, where they can increase production of lipids, including ceramide, a proapoptotic substance.[13,15]

GENERAL OVERVIEW OF FREE RADICAL BIOLOGY AND ANTIOXIDANTS AS DEFENSE MECHANISMS AGAINST ELEVATED CELLULAR GENERATION OF REACTIVE OXYGEN SPECIES

Oxygen is the most abundant element in the human body and accounts for approximately 65% of body mass.[16] Carl Wilhelm Sheele, Joseph Priestly, and Antoine-Laurent Lavoisier are credited with the discovery of oxygen.[16] Although essential for living creatures, the metabolism of oxygen gives rise to ROS, which can be a double-edged sword. ROS mediate killing of pathogenic bacteria by phagocytic cells and also act as second messengers for physiologic cellular signal transduction.[16] However, high oxygen levels can lead to excessive levels of oxidizing free radicals. In 1969 McCord and Fridovich reported the seminal observation that a substance, now referred to as superoxide dismutase (SOD), was catalyzing the dismutation of superoxide anion radicals to produce hydrogen peroxide and molecular oxygen.[17] Shortly thereafter, Babior and colleagues reported that one of the primary bactericidal actions of leukocytes was the enzymatic generation of superoxide.[18] Since then research into free radical mechanisms involved in the pathogenesis of a variety of human diseases has proliferated.

The term free radical refers to a chemical species that contains one or more unpaired electrons. ROS is a collective term that includes superoxide, hydrogen peroxide (H_2O_2), and hydroxyl radicals, among others. The term antioxidant is used to refer to any substance that can prevent or repair ROS-induced damage to proteins, lipids, and nucleic acids. Adverse events are collectively referred to as oxidative stress. Common antioxidant systems include (1) SOD and catalase, (2) the Gsh system, and (3) the Trx system.

1. SOD and catalase are considered together because they are the two enzymes responsible for converting superoxide to water. SOD converts superoxide to H_2O_2; catalase converts H_2O_2 to water. The two main species of SOD are Sod-1 and Sod-2. Sod-1 resides in the cytosol, nuclei, and mitochondrial intermembrane space; Sod-2 resides in the mitochondrial matrix. Catalase resides primarily in peroxisomes.
2. The Gsh system includes the reduced form of Gsh and the enzymes gamma-glutamylcysteine ligase and Gsh synthetase (Fig. 36.4). Glutathione reductase regenerates Gsh from Gsh disulfide. Gsh is synthesized from three amino acids: L-cysteine, L-glutamate, and glycine. Gsh can react directly with electrophilic compounds, such as reactive aldehydes, and lipid peroxidation products. Gsh is also the cofactor for glyoxalase-1, which is involved in the detoxification of glycolysis-derived alpha-oxoaldehyde and methylglyoxal, and thereby provides protection against hyperglycemia-induced oxidative stress (Fig. 36.4). Glutathione peroxidase (GPx) comprises a family of enzymes,

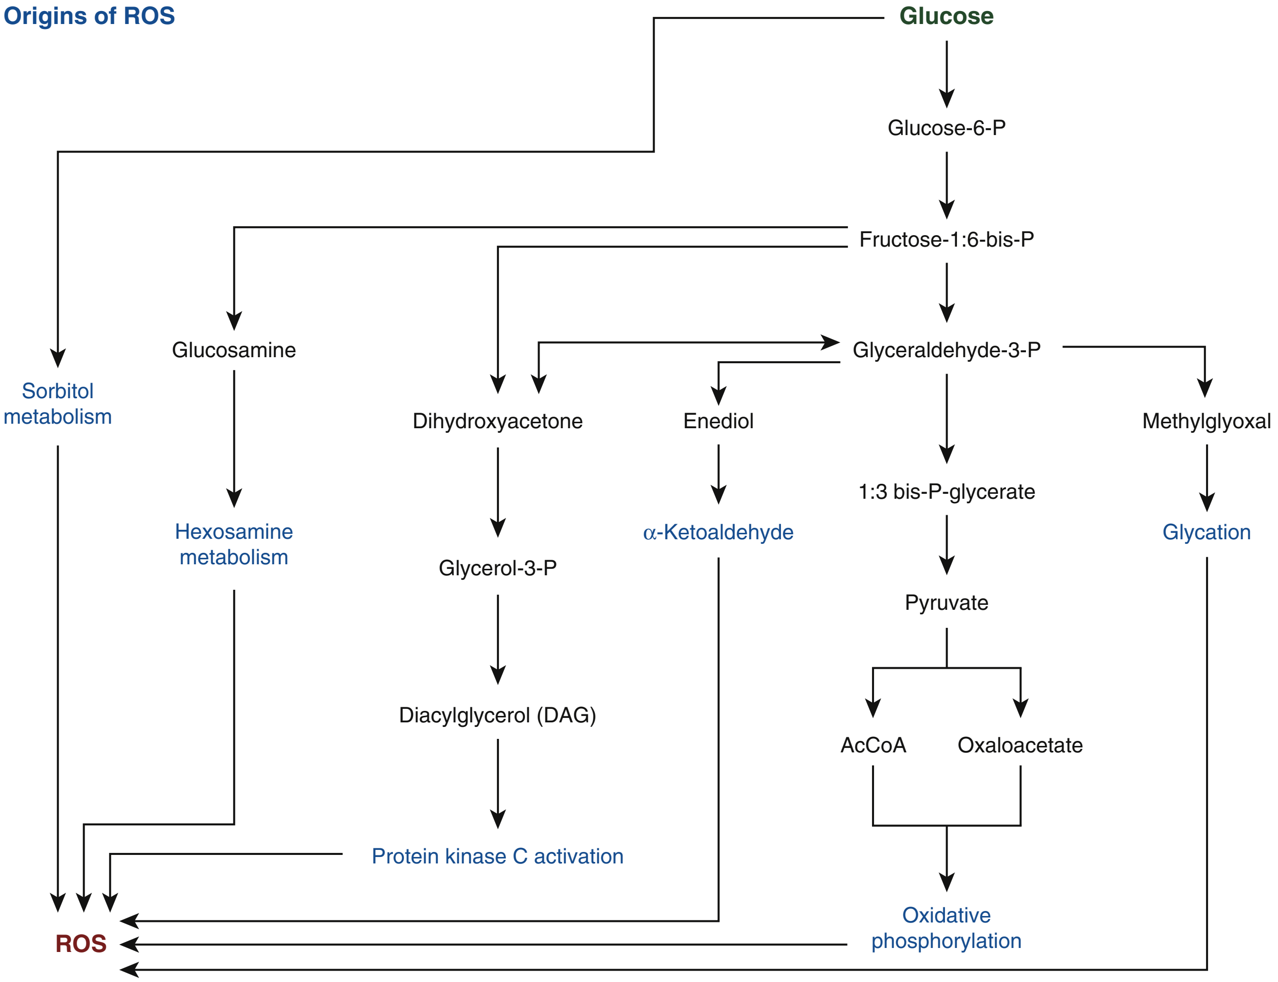

Fig. 36.1 Origins of reactive oxygen species. Six biochemical pathways by which glucose metabolism can form reactive oxygen species (*ROS*) are shown. Under physiologic conditions, glucose primarily undergoes glycolysis and oxidative phosphorylation. Under the pathophysiologic condition of hyperglycemia, excessive glucose levels can swamp the glycolytic process and be shunted to the other pathways, with the outcome of excessive ROS levels. *AcCoA,* Acetyl coenzyme A. including GPx1, 2, 3, and 4, which are selenoproteins. These enzymes decompose H_2O_2 and organic peroxides, which are among the major ROS that cause oxidative tissue injury. Consequently, these are among the most important antioxidant defenses against stress-associated disease pathology.

3. The Trx system includes Trx (also known as Txn), peroxiredoxin, Trx reductase, and sulfiredoxin. Trxs directly scavenge ROS; act as cofactors for peroxiredoxins, which are important enzymes for the detoxification of H_2O_2 and organic hydroperoxides; and are cofactors for methionine sulfoxide reductases, enzymes involved in protecting against oxidative protein damage and oxidative injury.

EVALUATION OF OXIDATIVE STRESS AND DEFECTIVE ENDOGENOUS ANTIOXIDANT RESPONSE IN β CELLS FROM THE POINTS OF VIEW OF THE GLUTATHIONE AND THIOREDOXIN PATHWAYS

Glutathione pathway. As with all cells, pancreatic β cells are dependent upon exogenous antioxidants to combat damage caused by endogenous ROS. However, the β cell is not among the cell types that are well-endowed with antioxidant systems, such as those found in the liver and kidneys. β cells have been reported to contain virtually no Gsh peroxidase or catalase and only modest amounts of superoxides dehydrogenases 1 and 2 and hemoxygenase.[19-21] This is a case of double jeopardy, because it is the dysfunction of synthesis and secretion of insulin by β cells that is primarily responsible for hyperglycemia, and yet it is that very defect that leads to chronic hyperglycemia and increased levels of ROS production in β cells as well as other tissues.[22] As such, this is an example of a feed-forward pathogenic mechanism wherein a functional defect in a cell causes an event that goes on to do further damage to the same cell (Fig. 36.5).

Studies have been designed to evaluate whether Gpx-1 enrichment of Gpx-1–deficient β cells may protect them against the adverse effects of hyperglycemia and increased levels of ROS. Beneficial effects were observed of transgenic overexpression of Gpx-1 specifically in β cells in diabetic rodents. The rodents developed increased levels of intranuclear MafA and Gpx-1, increased β cell mass, and normal levels of circulating glucose.[22-24] In other studies, the oral drug ebselen, which is a selenorganic Gpx mimetic, was fed to diabetic rodents. Beneficial effects were observed on β cell mass and islet function despite the presence of continuing hyperglycemia.[25] The importance of this observation derives from the fact that it is a very potent antioxidant that can be given orally and has been shown to be safe and effective in humans.[26-28]

Fig. 36.3 Transcription factor binding to the insulin promoter under normal and glucotoxic conditions. Under physiologic conditions, two major regulators of the insulin gene, Pdx-1 and MafA, are activated by rising glucose levels and leave the cytoplasm to enter the nucleus, where they bind to the insulin promoter to increase insulin mRNA levels. This process has been shown to be inhibited by chronic supraphysiologic levels of glucose and reactive oxygen species formation in multiple animal models of type 2 diabetes.

Fig. 36.4 Glutathione (Gsh) metabolism. Gsh synthesis is regulated by the enzymes glutamate–cysteine ligase catalytic subunit (*GCLC*) and Gsh synthetase, which use the substrates cysteine, glutamate, and glycine. Reduced Gsh is used by Gsh peroxidase to catabolize lipid peroxides and hydrogen peroxidase (*H2O2*) to form water and oxygen. Independently, superoxide ions are catabolized by superoxide dismutase (SOD) to form lipid peroxides and H_2O_2. Catalase independently also catabolizes H_2O_2 to form water and oxygen. Uniquely, the β cell is relatively deficient in both Gsh peroxidase and catalase, and therefore is reliant solely on SOD to catabolize reactive oxygen species. *GSSG*, Glutathione disulfide; *H2O*, water; *NADP*, nicotinamide adenine dinucleotide phosphate radical; *NADPH*, nicotinamide adenine dinucleotide phosphate; *O^-*, oxygen radical; *O_2*, oxygen.

KEY POINTS

- Pancreatic islet β cells are different than most body tissues in that they do not contain substantial levels of glutathione peroxidase or catalase, two essential endogenous antioxidants. This places β cells at heightened risk for damage by the excessive levels of reactive oxygen species caused by chronic hyperglycemia.

Nuclear factor erythroid-derived-2–related factor (Nrf2) upregulates the Kelch-like ECH-associated protein 1/Nrf2/antioxidant pathway, which is known as the master switch for gene expression of antioxidants (Fig. 36.6). The role of Nrf2 in the repair of oxidative stress-induced damage of β cells was examined in male ZDF rats. The rats were studied in the early phase of diabetes caused by eating a high-fat diet for short periods of time followed by 3 weeks' return to regular chow. While eating the high-fat diet the animals developed increased nuclear endogenous Nrf2 and hemoxygenase synthesis, reversal of hyperglycemia, and reversal of abnormal β cell structure in existing β cells[29] (Fig. 36.7). These studies suggested an innate ability for β cells that had undergone oxidative stress and structural damage to undergo self-repair via endogenous antioxidant synthesis. The conclusion for self-repair is strengthened by the fact that no evidence for increased apoptosis or increased β cell replication rates were observed during the short exposure to a high fat diet.

KEY POINTS

- If the adverse effects caused by hyperglycemia are reversed early in the course of developing chronic hyperglycemia, the β cell is capable of mounting an antioxidant defense via activation of cytoplasmic Nrf2 for translocation to the nucleus, where it stimulates genetic production of hemoxygenase.

Further deterioration of ß-cell function

Fig. 36.5 Glucose toxicity and oxidative stress. Chronic elevation of glucose levels causes increased oxidative phosphorylation, methylglycoxal/glycation, alpha-ketoaldehyde formation, protein kinase C activation, and hexosamine and sorbitol metabolism, resulting in production of reactive oxygen species (*ROS*), which in turn causes oxidative stress on cells. In the case of the β cell this is made worse by a low capacity of antioxidant enzymes, especially catalase and glutathione peroxidase, which leads to further deterioration of β cell function, and ultimately β cell death. This results in additional glucose elevation and increased expression of thioredoxin-interacting protein (*Txnip*), which inhibits thioredoxin function and thereby prevents the thioredoxin system from counteracting the growing oxidative stress the β cell is exposed to, leading to even more damage and worsening of the hyperglycemia.

Thioredoxin pathways. Members of the Trx system are ubiquitously expressed in all cells, including in pancreatic β cells, where they play a particularly important role[30] because of the low levels of other antioxidant systems.[19-21] The six known mammalian peroxiredoxins (Prdx1–6) detoxify H_2O_2 and reduce organic hydroperoxides, primarily by being oxidized at their cysteine residues. This hyperoxidation of the active-site cysteine leads to inactivation of the peroxiredoxins, which then depend upon reactivation by the oxidoreductase sulfiredoxin[31] (Fig. 36.8). Recently, Prdx3 has also been shown to be acetylated in response to high glucose, which adds to the β cell glucose toxicity and revealed yet another level of regulation.[32] Interestingly, there is also crosstalk between the Gsh and Trx systems. For example, sulfiredoxin not only reactivates peroxiredoxin, but also reverses cysteine glutathionylation.[33] In addition, ROS can lead to oxidation of free and protein-bound methionine residues, which impairs protein function. Methionine sulfoxide reductases catalyze the reduction of these residues back to methionine, and Trxs provide the reducing equivalents for this reaction.[34] Trxs also act as electron donors and modulate the activity of a variety of enzymes, including peroxidases and ribonucleotide reductases.[35]

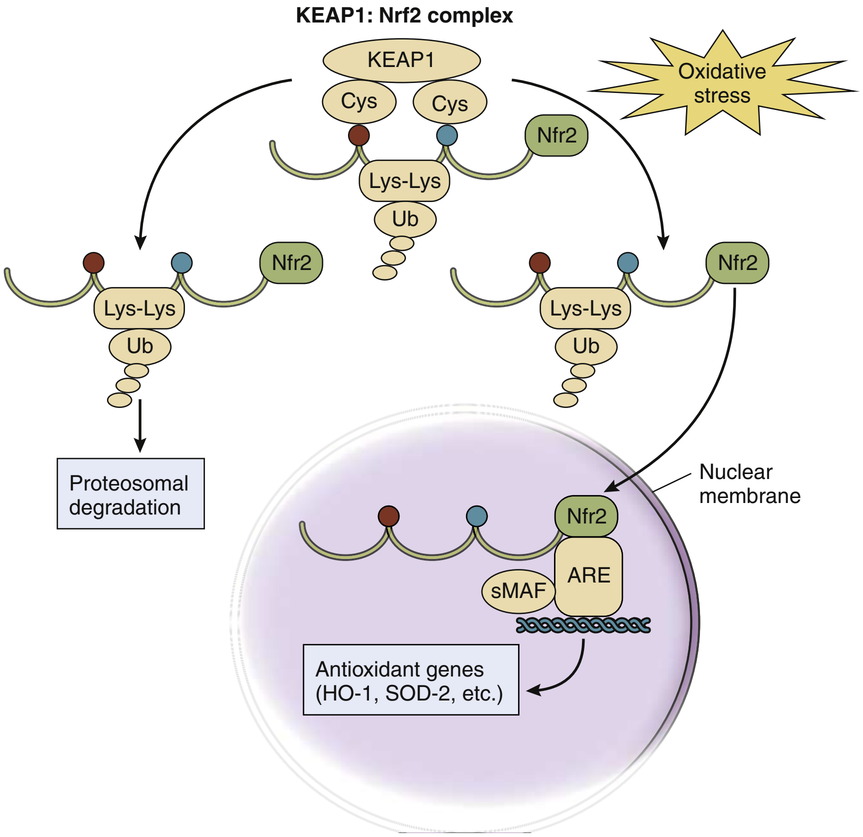

Fig. 36.6 **The Kelch-like ECH-associated protein 1 (*KEAP1*): nuclear factor erythroid-derived-2-related factor (*Nrf2*) complex.** Nrf2 is generally considered to be the master regulator of antioxidant gene transcription. Under quiescent conditions, Nrf2 is bound by KEAP1 in the cytoplasm, which ushers Nrf2 to proteosomes for degradation. However, in the face of oxidative stress, Nrf2 is released from KEAP1 and enters the nucleus, where it serves as a key activator of the promoter for antioxidant genes. *Cys,* Cysteine; *Lys,* lysine; *Ub,* ubiquitin.

However, Trxs primarily function as thioloxidoreductases that protect cells against oxidative stress by reducing oxidized proteins.[36] This cysteine thioldisulfide exchange reaction results in oxidation of the two cysteine residues of Trx. Reduction by Trx reductase returns Trx back to an active state[37,38] (Fig. 36.9). Taking advantage of the disulfide bonds present in the insulin molecule (see Chapter 32), reduction of insulin is being used as the classical test for the activity of Trx.[39] Trxs are highly conserved across species and essential for survival in mammals.[40] In humans there are two Trxs, a major cytosolic form (Trx1) and a mitochondrial form (Trx2), and loss-of-function mutation of either is embryonically lethal.

KEY POINTS

- The thioredoxin system is critical for survival and especially important in pancreatic β cells, where it helps to compensate for the relative lack of other antioxidant mechanisms. Thioredoxins function by reducing oxidized proteins and undergoing oxidation of their cysteines in the process.

Overall, the Trx system has been shown to be involved in multiple cellular processes, including cell proliferation and apoptosis.[37,41-43] Moreover, transgenic mouse studies have further established the critical role that this system plays in β cell biology and protection against diabetes. One of the first examples of this was the observation that β cell–specific overexpression of Trx prevented autoimmune and streptozotocin-induced diabetes in mice.[44]

In addition to their function as antioxidants, Trxs have been shown to interact with and inhibit the activity of apoptosis signal-regulating kinase 1 and thereby to protect cells from apoptosis[45,46] (Fig. 36.10). Most notably, Trxs interact with Trx-interacting protein (Txnip), a member of the arrestin family of proteins. Txnip inhibits the ability of Trxs to reduce oxidized proteins and thereby increases oxidative stress in the cell.[37,47-50] Consistent with this notion, increased Txnip expression has been linked to dysfunction and apoptosis, especially in β cells.[51,52] Txnip overexpression has also been found to lead to increased expression of the microRNA mir-204, which in turn targets the 3’ untranslated region of MafA, leading to decreased expression of this important insulin transcription factor and inhibition of insulin production.[53] Moreover, Txnip has been shown to represent a critical link between glucose toxicity and β cell death.[54] Interestingly, Txnip has been demonstrated to be upregulated in islets from donors with T1DM or T2DM,[55,56] in islets of different mouse models of diabetes, and in isolated islets or β cells exposed to high glucose.[51,54,57] Moreover, Txnip expression is induced by a variety of cellular stresses common in T1DM and T2DM, including endoplasmic reticulum stress and inflammatory cytokines.[58,59] Together this leads to a relentless cycle of oxidative stress, glucose toxicity and β cell damage (Fig. 36.5). In contrast, Txnip inhibition has emerged as an attractive therapeutic approach

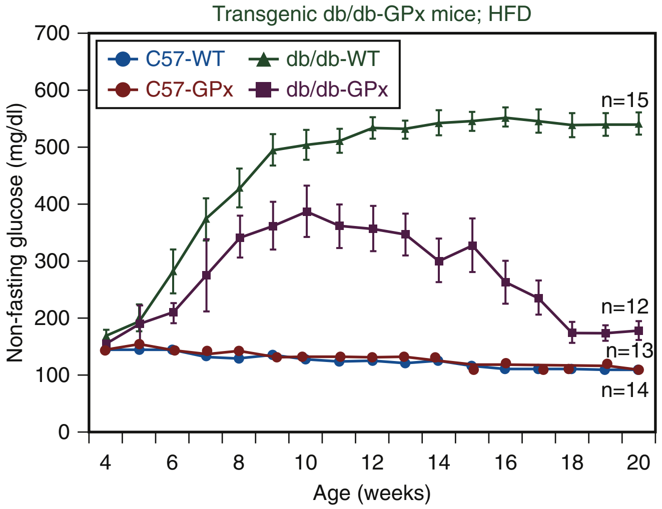

Fig. 36.7 Protection of mouse β cells by the *GPX-1* transgene against the glucotoxic effects of chronic hyperglycemia. Both normoglycemic, wild-type C57BL/6J (*C57-WT*) mice and db/db mice with a type 2 diabetic phenotype fed a high-fat diet (*HFD*) were used for these experiments. Transgenic expression of *GPX-1* had no effect in the C57-WT mice compared to C57-WT mice that did not express the transgene. However, transgenic expression of *GPX-1* initially dampened the onset of hyperglycemia, and with time reversed hyperglycemia, in the db/db mice, whereas the control db/db mice that did not express the transgene developed and maintained severe hyperglycemia. (From Harmon JS, Bogdani M, Parazzoli SD, et al. Beta-cell-specific overexpression of glutathione peroxidase preserves intranuclear mafa and reverses diabetes in db/db mice. *Endocrinology*. 2009;150:4855-4862.)

for T1DM and T2DM, as demonstrated by genetic deletion experiments[60,61] and pharmacological inhibition studies in mice[62,63] and humans.[64]

KEY POINTS

- Diabetes, glucose, and cellular stresses induce thioredoxin-interacting protein (Txnip) expression, and Txnip interaction with thioredoxin inhibits the antioxidative and antiapoptotic effects.

BRIEF OVERVIEW OF THE CONTRIBUTIONS OF OXIDATIVE STRESS TO SECONDARY COMPLICATIONS OF DIABETES

Although β cells may be particularly sensitive, other tissues including those affected by secondary diabetes complications are also negatively impacted by glucolipotoxicity, inflammation, and oxidative stress (see Chapter 32). The mechanisms involved are similar, including excess glucose resulting in increased mitochondrial production of ROS in the heart (cardiomyopathy), kidney (nephropathy), eye (retinopathy), and peripheral nervous system (neuropathy), and SOD and catalase as well as the Gsh and Trx regulatory pathways serving as the major defense mechanisms against the ensuing cell dysfunction, damage, and apoptosis.[65,66] (Fig. 36.11). In fact, upregulation of these antioxidant pathways by transgenic overexpression or, more frequently, indirectly by downregulation of Txnip, the natural Trx inhibitor, has been shown

Fig. 36.11 **Generalized effects of oxidative stress and antioxidant pathways.** Aside from severe detrimental effects on islet β cells, reactive oxygen species (*ROS*) also impact other organ systems affected by diabetes, including the heart, the kidney, the eye, the immune system, and the liver. There they contribute to secondary diabetes complications such as cardiomyopathy, nephropathy, and retinopathy. The antioxidant glutathione (*GSH, GPx*), superoxide dismutase (*SOD*) and thioredoxin (*TRX, PRDX*) regulatory pathways oppose and protect against these damaging effects.

to result in protective effects. These beneficial effects were found in the context of inflammation in retinal injury,[67-69] vascular oxidative stress, and myocardial ischemia reperfusion,[70,71] as well as mesangial cell and podocyte apoptosis and dysregulation of tubular autophagy in diabetic nephropathy.[72-74] In addition, Txnip has been shown to be involved in peripheral glucose metabolism[63,75] and play a critical role in diet-induced insulin resistance of T2DM.[61,76] Moreover, oxidative stress has recently also emerged as an important factor in the autoimmunity of T1DM,[77] as well as in diabetes-associated metabolic liver disease.[78] Taken together, oxidative stress represents an integral aspect of metabolic disease, diabetes, and pancreatic β cell dysfunction.

KEY POINTS

- Oxidative stress and the systems controlling it not only play a major role in β cell pathobiology, but are also critical in the context of diabetes complications affecting many organ systems.
